Congenital short penis has been described in bulls and may be associated with short retractor penis muscles, which prevent full erection. Bulls may breed satisfactorily in the first season, but copulation becomes impossible as their body size increases.

Short retractor penis muscle may occur congenitally or after injury to the penis or prepuce. Affected bulls have normal libido, but during attempted service the penis is only partially protruded from the sheath and the ejaculatory thrust does not occur. Failure of erection in bulls may be a congenital condition but is generally a sequela of trauma and/or hematoma of the penis.

Congenital vascular shunts have been described in bulls with partial erection or erection failure.

Hypospadias is an abnormal opening of the urethra due to failure or incomplete closure of the embryonic urethral groove.

FEMALE GENITAL ABNORMALITIES

Ovarian Abnormalities: The most common congenital abnormality of the ovary is ovarian dysgenesis or ovarian hypoplasia. Ovarian dysgenesis has been described in several domestic animal species and has been associated with various chromosomal abnormalities (monosomy X or Turner syndrome, trisomy XXX, or Klinefelter syndrome XXY). The ovaries are very small and lack follicular activity.

Segmental Aplasia of the Paramesonephric Ducts:

The paramesonephric ducts are paired embryonic ducts that develop into the anterior vagina, cervix, uterus, and uterine tube. Segmental aplasia of the paramesonephric ducts results in anomalies of those organs. The aplasia (obstruction) may be located in a segment of the uterine tube, uterine horn, cervix, or vagina. Ovarian development is normal. Accumulation of secretions proximal to the obstruction occurs secondarily (hydrosalpinx, hydrometra, mucometra, colpometra).

Segmental aplasia of the uterus may involve one horn (resulting in a condition called uterus unicornis), both horns, or only part of one horn (which may result in cystic dilatation of the uterine horn anterior to the area of dilatation). Uterus unicornis has been described in several domestic animal species. The condition seems to be relatively common in camelids. These females can become pregnant and carry the pregnancy to term. Cervical aplasia has been described in a few cases but is not as common.

True persistence of the hymen or imperforation of the hymen is the most commonly reported paramesonephric duct anomaly in domestic animals. Fluid accumulates in the vagina and uterus, resulting in protrusion of the hymen at the vulva when the animal is lying down or straining. Hymenal defects are most common in white Shorthorn cattle (white heifer disease).

Cervical Abnormalities: Double external os of the cervix is due to a failure of the paramesonephric ducts to fuse. It may present as a band of tissue caudal to, or in, the external os of the cervix. In other cases, there is a true double external os opening into a single caudal part of the cervical

canal. Affected cows usually conceive normally. Rarely, a true double cervix, with a complete septum between the two cervical canals, each opening into its respective uterine horn (uterus didelphys), occurs.

Vaginal and Vulvar Abnormalities: **Vaginal stricture or vestibulovaginal hypoplasia** has been described in mares, dogs, and camelids.

Gartner's ducts, located beneath the mucosa of the floor of the vagina, may develop multiple cysts, which are generally of no clinical significance.

Vulvar atresia or hypoplasia (atresia vulvi) has been described primarily in

camelids. In extreme cases, the labia are completely fused. The condition is believed to be due to an autosomal recessive gene.

Rectovaginal constriction is a connective tissue disorder of Jersey cattle characterized by stenosis of the anus and/or vestibulovaginal sphincter. Bilateral stenosis of the milk veins has also been described and results in udder edema and ischemic necrosis. It is a simple autosomal recessive defect. Anal stenosis renders transrectal palpation difficult. Affected females experience severe dystocia. The prevalence of the disease has been substantially reduced because of identification of carrier bulls.

ABORTION IN LARGE ANIMALS

Abortion is the termination of pregnancy after organogenesis is complete but before the expelled fetus can survive. If pregnancy ends before organogenesis, it is called early embryonic death. A dead, full-term fetus is a stillbirth (its lungs are not inflated). Many etiologies of abortion also cause stillbirths, mummification, and weak or deformed neonates.

The etiologic diagnosis of abortion in livestock is a difficult and often frustrating task. The diagnostic success rate is relatively low and variable: 30%–40% for bovine, 60%–65% for ovine, 35%–40% for porcine, and from <10% to 90% in equine abortion cases submitted to diagnostic laboratories. The diagnostic success rate in camelids is very low except in outbreaks. Numerous factors complicate diagnosis. Often, abortion follows initial infection by weeks or months, so the causative agent is no longer apparent when abortion occurs. Expulsion may follow fetal death by hours or days, with lesions obscured by autolysis. Fetal membranes and the aborted fetus are usually contaminated by environmental agents before examination. Many sporadic abortions are likely the result of noninfectious (ie, toxic or genetic) causes, about which much less is known than infectious causes; many diagnostic laboratories are not equipped or staffed to deal with these causes of abortion.

Another problem in determining the cause of abortions is improper or inadequate specimen selection and handling. The best specimen is the complete fetoplacental unit

in fresh condition, along with maternal serum. The placenta and fetus should be cleaned with water or saline, packed in clean plastic bags, chilled (but not frozen), and rapidly transported to the diagnostic laboratory. In most cases, autolysis proceeds at a much slower rate in fetuses than in carcasses of animals born alive. If chilled as soon as possible, most fetuses will be suitable for examination, even if they do not reach the laboratory for 1–2 days. Fetal pigs, sheep, and goats are usually small enough to transport or ship whole with the placenta. If there are multiple fetuses, three to five should be submitted with their placentas. It is best to submit calves and foals whole, but in many cases it is more convenient to perform a necropsy and collect samples for submission.

The specimens routinely used for testing vary somewhat between diagnostic laboratories, but a basic set of samples that will allow thorough examination includes stomach or abomasal contents; heart blood or fluid from a body cavity; unfixed lung, liver, kidney, and spleen (some laboratories also request tissues such as thyroid glands, thymus, heart, brain, abomasum, and stomach); placenta (if available); and dam's serum. These should be submitted in sterile containers to allow for microbiologic cultures. Because they are always contaminated, placentas should not be mixed with other tissues.

Representative samples of the following should also be submitted in 10% buffered formalin for histopathologic

examination: lung, liver, heart, kidney, spleen, brain, skeletal muscle, thyroid, adrenal glands, intestines, and placenta (see p 1584). In a large majority of cases, gross lesions other than signs of autolysis (increased pleural and peritoneal fluid and blood-tinged subcutaneous edema) are not present. However, if lesions are found, fresh and formalin-fixed samples of affected tissues should be included.

Most agents, especially bacteria and fungi, infect the placenta and thus gain entry into the amniotic fluid, which is swallowed by the fetus. Stomach contents can be obtained aseptically, making it the best specimen for detection of fungi and most bacteria. Isolation from the stomach contents is much easier than from the placenta, which is always heavily contaminated. Lungs, liver, spleen, and kidneys are also good for culture. Several agents (eg, fungi, *Chlamydia*, *Coxiella*) primarily affect the placenta; failure to include placenta decreases the probability they will be identified. Fetuses sometimes produce antibodies to certain agents (eg, bovine viral diarrhea virus, *Neospora* spp, *Leptospira* spp), and fetal serum or fluid from a body cavity can be tested for antibodies. The presence of precolostral antibodies is evidence of in utero exposure.

A single antibody titer in the dam rarely provides evidence of abortion caused by a particular agent unless background herd titer levels are known. High maternal titers may as likely be the reason an animal did not abort due to that agent, but absence of a titer can be used to exclude an agent. Antibody titers to agents with control programs (eg, *Brucella abortus*, pseudorabies virus) are always significant, even if the abortion was caused by something else. Demonstration of a 4-fold increase in antibody titer is required to prove active infection by a specific agent. Often, abortion occurs weeks or months after initial infection of the dam, and her titer is stable or declining at the time of abortion. Paired serum samples obtained 2 wk apart from 10% of the herd or a minimum of 10 animals often demonstrate seroconversion and provide evidence of active infection in the herd.

ABORTION IN CATTLE

See also MANAGEMENT OF REPRODUCTION: CATTLE, p 2171.

Given the low diagnostic success rate, the high cost of laboratory work, and the low profit margin in both the beef and dairy industries, veterinarians should not attempt to make an etiologic diagnosis in every

abortion. Instead, veterinarians should become concerned if fetal loss is >3%–5% per year or per month.

Noninfectious Causes

The actual incidence of abortions in cows due to genetic factors is unknown. Some genetically caused abortions may not have phenotypically recognizable lesions. Most lethal genes cause early abortion or early embryonic death.

Vitamins A and E, selenium, and iron have been implicated in bovine abortions, but documentation based on experiments is available only for vitamin A.

Heat stress causes fetal hypotension, hypoxia, and acidosis. High maternal temperature due to pyrexia may be more important than environmentally induced heat stress.

Although severe trauma may rarely result in abortion (the bovine fetus is well protected by the amniotic fluid), farmers undoubtedly blame too many abortions on the cow “getting bumped.”

A number of toxins can cause abortion in cows. Ponderosa pine needles can cause abortion if ingested in the last trimester; the cows may become moribund after delivery and hemorrhage excessively. The main abortifacient compounds in Ponderosa pine needles are isocupressic acid and labdane resin. Locoweed (*Oxytropis* or *Astragalus* sp) contains an indolizidine alkaloid that can affect the corpus luteum, chorioallantois, and neurons, resulting in abortion or deformities. Broomweed (*Gutierrezia microcephala*) ingestion can also cause abortion, as can coumarins from rat poison, many grasses, or moldy sweet clover. Sodium iodide, IV, has been contraindicated in pregnant cows, but no abortions or adverse effects occurred in pregnant cows treated with a single high dose in some studies. Mycotoxins, especially those with estrogenic activity, have been implicated in bovine abortions. Nitrates or nitrites have also been incriminated, but experimental evidence is controversial.

Infectious Causes

Neosporosis: *Neospora caninum* is found worldwide and is the most common cause of abortion in dairy and beef cattle in many parts of the USA. Dogs and coyotes are definitive hosts for *N caninum* and can be the source of infection. Abortion can occur any time after 3 mo of gestation but is most common between 4 and 6 mo of gestation. *Neospora* can be associated with sporadic abortions or abortion storms, and

repeat abortions in cows have been reported. Most infections result in an asymptomatic congenitally infected calf. Some infected calves are born with paralysis or proprioceptive deficits. Cows are not clinically ill, and placental retention is not common. The fetus is usually autolyzed or, in a few cases, mummified and rarely has gross lesions. Microscopically, nonsuppurative inflammation is common in the brain, heart, and skeletal muscles. Organisms can be identified in these tissues and the kidneys by immunohistochemical staining and PCR. Many late gestation fetuses have precolostral antibodies. They remain infected for years and possibly for life. Vertical transmission is common. During pregnancy, *Neospora* organisms can become activated and infect the fetus. This is thought to be the most common source of infection. There is no treatment. Strict hygiene to prevent fecal contamination of feed by dogs or coyotes may aid in prevention. A commercial vaccine is available. (See also p 663.)

Bovine Viral Diarrhea (BVD): In several surveys, BVD was the most commonly diagnosed virus in bovine abortion cases. The pathology of BVD in the developing fetus is complex. Infection before insemination or during the first 40 days of pregnancy results in infertility or embryonic death. Infection between 40 and 125 days of pregnancy results in birth of persistently infected calves if the fetus survives. Fetal infection during the period of organogenesis (100–150 days) may result in congenital malformations of the CNS (cerebellar hypoplasia, hydrancephaly, hydrocephalus, microencephaly, and spinal cord hypoplasia). Congenital ocular defects have also been seen (cataracts, optic neuritis, retinal degeneration, microphthalmia). After 125 days of gestation, BVD may cause abortion, or the fetal immune response may clear the virus. Diagnosis is by identification of BVD virus by isolation, immunologic staining, PCR, or detection of precolostral antibodies in aborted calves. The virus is present in a wide variety of tissues, but the spleen is the tissue of choice. Rising antibody titers to BVD in aborting animals or herdmates is diagnostic of recent infection. BVD virus is immunosuppressive and is found in many fetuses infected by other agents (eg, bacteria, *N. caninum*). Outbreaks of abortions by organisms that normally cause sporadic abortion should raise suspicion of possible concurrent BVD virus infection. Prevention should focus on removal of persistently infected cattle and herd vaccination. (See also p 267.)

Infectious Bovine Rhinotracheitis (IBR, Bovine Herpesvirus 1): Infectious bovine rhinotracheitis (IBR) is a major cause of viral abortion in the world, with abortion rates of 5%–60% in nonvaccinated herds. The virus is widespread, causes latent infections, and can recrudesce; therefore, any cow with a positive IBR titer is a possible carrier. The virus is carried to the placenta in WBCs; over the next 2 wk to 4 mo, it causes a placentitis, then infects the fetus and kills it in 24 hr. Abortion can occur any time but usually is from 4 mo to term. Autolysis is consistently present. Occasionally, there are small foci of necrosis in the liver, but in a large majority of cases there are no gross lesions in the placenta or fetus. Microscopically, small foci of necrosis with minimal inflammation are consistently present in the liver. Necrotizing vasculitis is common in the placenta. Diagnosis can be made by immunologic staining of the kidney, lung, liver, placenta, and adrenal glands. IBR virus can be isolated from ~50% of infected fetuses (most successfully from the placenta). In most cases, maternal titers have peaked by the time of abortion. In abortion storms, rising titers can often be demonstrated in herdmates. Control is by herd vaccination; intranasal, modified-live virus, and killed vaccines are available. (See also p 1434.)

Leptospirosis: The pathogenic leptospires were formerly classified as serovars of *Leptospira interrogans*, but they have been reclassified into 7 species with >200 recognized serovars. *Leptospira* serovars Grippotyphosa, Pomona, Canicola, and Icterohaemorrhagiae usually cause abortions in the last trimester, 2–6 wk after maternal infection. Serovar Hardjo is host adapted to cattle and can establish lifelong infections in the kidneys and reproductive tracts. In addition to third trimester abortions, serovar Hardjo reduces conception rates in carrier cows and cows bred to carrier bulls.

Although dams may show clinical signs of leptospirosis, most abortions are in otherwise healthy cattle. Abortion rates vary from 5%–40% or more. The leptospires cause a diffuse placentitis with avascular, light tan cotyledons and edematous, yellowish intercotyledonary areas. The fetus usually dies 1–2 days before expulsion and therefore is autolyzed. Occasionally, calves are born alive but weak. Fetuses infected with serovar Pomona may show icterus. There are no specific lesions, but placenta and fetus should be submitted to the laboratory for fluorescent antibody staining or PCR testing for *Leptospira*.

Although maternal titers are probably waning by the time of abortion, an initial titer of >1:800 may be suspicious. Approximately one-third of cows aborting because of serovar Hardjo have titers of <1:100 at the time of abortion. Cows infected with serovar Hardjo can shed the organism in urine throughout life. For other serovars, the dam's urine can be cultured or examined for leptospires within 2 wk of abortion.

For control, sources of infection (such as feed or water contaminated by dogs, rats, or wildlife) should be identified and eliminated. Vaccination with a five-way bacterin every 6 mo provides good protection against serovars Grippotyphosa, Pomona, Canicola, and Icterohaemorrhagiae but does not protect against infection and renal shedding by serovar Hardjo. New monovalent serovar Hardjo vaccines that prevent infection, but do not cure existing infections, are available.

The following treatments have been found to eliminate the renal carrier state: a single injection of oxytetracycline (20 mg/kg, IM), a single injection of tilmicosin (10 mg/kg, SC), ceftiofur (5 mg/kg/day, IM, for 5 days or 20 mg/kg/day, IM, for 3 days), or amoxicillin (15 mg/kg, IM, two injections 48 hr apart).

Leptospirosis is zoonotic, and urine and milk of dams may be infective for up to 3 mo, except for Hardjo, in which case cows can be infective for life if not treated. (See also p 646.)

Brucellosis: Brucellosis (Bang's disease) is a threat in most countries where cattle are raised. In the USA, active control programs, including test, slaughter, and heifer vaccination, have greatly decreased its incidence. Brucellosis causes abortions in the second half of gestation (usually ~7 mo), and ~80% of unvaccinated cows in later gestation will abort if exposed to *Brucella abortus*. The organisms enter via mucous membranes and invade the udder, lymph nodes, and uterus, causing a placentitis, which may be acute or chronic. Abortion or stillbirth occurs 2 wk to 5 mo after initial infection. Affected cotyledons may be normal to necrotic, and red or yellow. The intercotyledonary area is focally thickened with a wet, leathery appearance. The fetus may be normal or autolytic with bronchopneumonia. Diagnosis can be made by maternal serology combined with fluorescent antibody staining of placenta and fetus or isolation of *B abortus* from placenta, fetus (abomasal contents and lung), or uterine discharge. Prevention is by calfhood vaccination of heifers.

Brucellosis is a serious zoonosis and a reportable disease, and the appropriate authorities should be contacted. (See also p 1348.)

Mycotic Abortion: Fungal placentitis due to *Aspergillus* sp (septated fungi, 60%-80% of cases), or to *Mucor* sp, *Absidia*, *Rhizopus* sp, and a few other nonseptated fungi, is an important cause of bovine sporadic abortion. Abortions occur from 4 mo to term and are most common in winter. It is believed the fungi gain entry through the oral or respiratory tracts and travel hematogenously to the placenta. Placentitis is severe and necrotizing. Cotyledons are enlarged and necrotic with turned-in margins. The intercotyledonary area is thickened and leathery. Adventitious placentation is common. The fetus seldom is autolyzed, although it may be dehydrated; ~30% have gray ringworm-like skin lesions principally involving the head and shoulders. The diagnosis is based on the presence of fungal hyphae associated with necrotizing placentitis, dermatitis, or pneumonia. Fungi can also be isolated from the stomach contents, placenta, and skin lesions. Isolation must be correlated with microscopic and gross lesions to exclude contamination after abortion.

For control, moldy feed should be avoided. (See also p 3005.)

Trueperella pyogenes: *Trueperella* (*Arcanobacterium*) *pyogenes* causes sporadic abortion at any stage of pregnancy. Rarely, the incidence in a herd may reach epizootic levels. The bacterium is present in the nasopharynx of many healthy cows and in abscesses. It is not normally present, even as a contaminant, in fetuses or fetal membranes, and isolation is almost always significant. It gains entry to the bloodstream and causes an endometritis and placentitis, which is diffuse with a reddish brown to brown color. The fetus is usually autolyzed, with fibrinous pericarditis, pleuritis, or peritonitis possible.

Bronchopneumonia may be evident on histopathology, but *T pyogenes* is best cultured from placenta or abomasal contents. Abortion is usually sporadic, and no effective bacterin is available.

Trichomoniasis: *Tritrichomonas foetus* infection causes a venereal disease that usually results in infertility but occasionally causes abortion in the first half of gestation. Placentitis is relatively mild, with hemorrhagic cotyledons and thickened intercotyledonary areas covered with flocculent

exudate. The placenta is often retained, and there may be pyometra. The fetus has no specific lesions, although *T.foetus* can be found in abomasal contents, placental fluids, and uterine discharges. Infected cows typically clear the organism within 20 wk, but bulls, especially those infected after 3 yr of age, can become lifelong carriers. There is no legal, effective treatment for individual animals. Herd treatment is based on identifying and segregating pregnant females from "at-risk" females for ≥5 mo and by identifying and culling all infected bulls. Prevention is by artificial insemination or natural insemination using noninfected bulls. A killed, whole-cell vaccine is available for use in cows. (See also p 1384.)

Campylobacteriosis: *Campylobacter fetus venerealis* causes venereal disease that usually results in infertility or early embryonic death but occasionally causes abortion between 4 and 8 mo of gestation. *C.fetus fetus* and *C.jejuni* are transmitted by ingestion and subsequent hematogenous spread to the placenta. Both cause sporadic abortions, usually in the last half of gestation. The fetus can be fresh with partially expanded lungs or severely autolyzed. Mild fibrinous pleuritis and peritonitis may be noted, as well as bronchopneumonia. Placentitis is mild with hemorrhagic cotyledons and an edematous intercotyledonary area. *Campylobacter* spp can be identified by darkfield examination of abomasal contents or culture of placenta or abomasal contents. Isolation and identification of the species involved is important if vaccination is to be instituted. Venereal campylobacteriosis can be controlled by artificial insemination and vaccination. *Campylobacter* spp are zoonotic, and *C.jejuni* is an important cause of enteritis in people. (See also p 1347.)

Listeriosis: *Listeria monocytogenes* can cause placentitis and fetal septicemia. Abortions are usually sporadic but may affect 10%–20% of a herd. Abortion is at any stage of gestation, and the dam may have fever and anorexia before the abortion; retained placenta is common. The fetus is retained for 2–3 days after death, so autolysis may be extensive. Fibrinous polyserositis and white necrotic foci in the liver and/or cotyledons are common. Diagnosis is by culture of *Listeria* from fetus or placenta. There is no available bacterin. Listeriosis is a reportable disease in many areas and is a serious zoonosis, with spread possible through improperly pasteurized milk. (See also p 656.)

Chlamydiosis: *Chlamydia abortus*, the cause of enzootic abortion of ewes, causes sporadic abortion in cattle. Most abortions occur near the end of the last trimester, but they can occur earlier. Placental lesions consist of thickening and yellow-brown exudate adhered to the cotyledons and intercotyledonary areas. Histologically, placentitis is consistently present, and pneumonia and hepatitis can be found in some cases. *C.abortus* can be identified by examination of stained smears of the placenta or by ELISA, fluorescent antibody staining, PCR, or isolation in embryonated chicken eggs or cell culture. Organisms can often be identified in the lungs and liver but not as consistently as in the placenta. There are no vaccines for cattle, although they are produced for sheep (see p 1338). The bacterium is zoonotic, occasionally producing life-threatening disease and abortion in pregnant women.

Ureaplasma diversum Infection: *Ureaplasma diversum* is a common inhabitant of the vagina and prepuce of cattle that also causes abortions. Abortions are usually single, but severe outbreaks occur on occasion. The infection may also result in stillbirths and birth of weak calves. Most fetuses are aborted in the third trimester and are well preserved. The cows are not sick, but retained placentas are common. Placentitis and a necrotic amniotic membrane are common features. The intercotyledonary areas are usually thickened and sometimes contain areas of fibrin deposition and hemorrhage. There are no gross lesions in the fetus. Microscopically, there is nonsuppurative placentitis and pneumonia characterized by accumulations of lymphocytes around bronchi and by diffuse alveolitis. Diagnosis is by isolation of *U.diversum* from the placenta, lungs, and/or abomasal contents.

Epizootic Bovine Abortion (Foothill Abortion): Epizootic bovine abortion is localized to the foothill region surrounding the Sacramento/San Joaquin Valley and the Eastern Sierra Nevada range of California, Oregon, and Nevada. Epizootic bovine abortion usually causes a protracted abortion storm affecting primarily heifers or cows recently introduced to the geographic region; however, abortion can occur 3–5 mo after leaving the endemic area. Abortion is usually in the last trimester, and rates may be as high as 60%. The animals abort without illness, and the fetus is seldom autolyzed. Although the etiologic agent has not been definitively determined, it is

transmitted by the argasid tick *Ornithodoros coriaceus* and is believed to be an unnamed bacterium in the Myxobacteria family (order Myxococcales). The aborted fetus may have hepatomegaly, splenomegaly, and generalized lymphomegaly. Microscopically, there is marked lymphoid hyperplasia in the spleen and lymph nodes and granulomatous inflammation in most organs. Fetal IgG is increased. Cows seldom abort in subsequent pregnancies, and heifers are often exposed to endemic areas before breeding age in an effort to prevent abortions.

Bluetongue: Bluetongue is caused by an Orbivirus with 24 serotypes and is transmitted by biting midges of the genus *Culicoides*. Historically, bluetongue occurred from approximately latitude 35°S to 40°N, except in the western USA, where it occurs to 45°N. After introduction of an attenuated, live virus serotype 10 vaccine in the 1950s, abortion, mummification, stillbirth, and the birth of live offspring with CNS malformations occurred in cattle and sheep. Since then, multiple bluetongue serotypes have been identified as causes of similar reproductive losses in cattle and sheep. Attenuation of bluetongue virus can increase its ability to cross the placenta. There is evidence that before 2007, reproductive losses were caused by attenuated bluetongue vaccine viruses, either by vaccination of pregnant animals or by spread of vaccine virus in nature by *Culicoides* spp.

In 2006, serotype 8 bluetongue virus appeared, spread, and became endemic across northwestern Europe (north of 50°N), where bluetongue was previously unknown. Beginning in 2007, abortions and birth of “dummy” calves with brain malformations occurred in bluetongue-infected herds; affected calves were documented to have been infected in utero. Since then, many such cases have been reported. Diagnosis is by identification of precolostral antibodies to bluetongue or identification of the virus by PCR. Brain, spleen, and whole blood are the preferred samples from fetuses and neonates for PCR. Control of bluetongue is by vaccination and management procedures to reduce exposure to biting midges. Modified-live and inactivated vaccines are available, but their availability and use varies between countries. (See also p 738.)

Other Causes of Abortion: Akabane virus (where present) causes abortion and fetal anomalies. Parainfluenza-3 virus

causes abortion in experimentally inoculated seronegative cattle, but is seldom, if ever, diagnosed in field cases of abortion. Occasionally, *Salmonella* spp cause abortion storms. The cows are usually sick, and the fetuses and placentas are autolyzed and emphysematous. *Salmonellae* can be isolated from the abomasal contents and fetal tissues and from uterine fluids and the dams' feces. *Mycoplasma* spp, *Histophilus somni*, and a wide variety of other bacteria can also cause sporadic abortions in cattle. Schmallenberg virus, discovered in Europe in 2011, belongs to the Simbu serogroup and has been associated with infertility, abortion, and fetal malformation in several ruminant species.

ABORTION IN SHEEP

See also MANAGEMENT OF REPRODUCTION: SHEEP, p 2212.

Abortion in ewes, as in cows, is not always easily diagnosed. Although many of the toxins that cause abortion in cows also cause problems in ewes, others such as *Verratrum californicum* and kale seem unique to the ewe. Subterranean clover (*Trifolium subterraneum*) is a common cause of early embryonic death and abortion in sheep. The major infectious agents causing abortions in sheep are *Campylobacter* sp, *Chlamydia* sp, *Toxoplasma* sp, *Listeria* sp, *Brucella* sp, *Salmonella* sp, border disease virus, and Cache Valley virus.

Campylobacter spp Infection

(Vibriosis): Infection with *Campylobacter fetus fetus*, *C jejuni jejuni*, and *C lari* results in abortions in late pregnancy or stillbirths. The route of infection is oral. Ewes may develop metritis after expelling the fetus. Placentitis occurs with hemorrhagic necrotic cotyledons and edematous or leathery intercotyledonary areas. The fetus is usually autolyzed, with 40% having orange-yellow necrotic foci (1–2 cm diameter) in the liver. Fetuses may have accumulated serosanguineous fluid in the thoracic and peritoneal cavities. Diagnosis relies on finding *Campylobacter* organisms in darkfield or fluorescent antibody preparations or by isolation from fetal abomasal contents, liver, and lungs, or from placental smears or in uterine discharge. Identification of the species involved is important, because in some areas *C jejuni* is as common as *C fetus*, and some vaccines do not include *C jejuni*. Strict hygiene is necessary to stop an outbreak. Use of tetracyclines may help prevent exposed

ewes from aborting. However, many isolates may be resistant to tetracycline. The disease tends to be cyclical, with epizootics occurring every 4–5 yr; therefore, vaccination programs, which help prevent outbreaks, should be consistently practiced. *C. jejuni* is zoonotic and is a common cause of enteritis in people.

Enzootic Abortion of Ewes (EAE):

Chlamydia abortus is the cause of EAE, which is characterized by late-term abortions, stillbirths, and weak lambs. *C. pecorum* is the cause of chlamydial arthritis and conjunctivitis of sheep. EAE occurs worldwide, except for in Australia and New Zealand, and is most important in intensively managed sheep. Abortions occur during the last 2–3 wk of gestation regardless of when infection occurs, and the fetuses are fresh with minimal autolysis. Gross lesions in the fetus are rare and may include ascites, lymphadenopathy, and liver congestion. There is placentitis with necrotic, reddish brown cotyledons and thickened brown intercotyledonary areas covered by exudate. Chlamydial elementary bodies can be found by examination of Gimenez- or Giemsa-stained smears of the placenta or vaginal discharge, but the organisms cannot be differentiated from *Coxiella burnetii*, which occasionally causes abortion in sheep.

Definitive diagnosis is by identification of *C. abortus* by ELISA, fluorescent antibody staining, PCR, or isolation. Ewes seldom abort more than once; but they remain persistently infected and shed *C. abortus* from their reproductive tract for 2–3 days before and after ovulation. Rams can be infected and transmit the organism venereally. Control consists of isolating all affected ewes and lambs and treating in-contact ewes with long-acting oxytetracycline or oral tetracycline. *C. abortus* bacterins are available and reduce abortions. In parts of Europe, a modified-live vaccine is available for use.

C. abortus is zoonotic, but human cases are rare. All have involved pregnant women, who developed life-threatening illness. Only in a few cases in which the fetus was delivered by cesarean section did the infant survive. Pregnant women should not work with pregnant sheep, especially if abortions are occurring.

Border Disease: Border disease occurs worldwide and is an important cause of embryonic and fetal deaths, weak lambs, and congenital abnormalities. It is caused by a pestivirus closely related to bovine viral

diarrhea (BVD) virus and classical swine fever (hog cholera) virus. Infection of susceptible animals occurs after introduction of persistently infected animals. Venereal transmission from shedding rams is possible. Abortion can occur at any stage of gestation. There are no clinical signs in the dam, except for a mild fever and leukopenia in a few cases. Live infected fetuses usually are undersized, and they often have congenital tremors and an abnormally hairy coat (hairy shaker lambs). Diagnosis is by identification of border disease virus in the placenta or fetal tissues (kidneys, lungs, spleen, thyroid glands, abomasum) by fluorescent antibody staining, virus isolation, or demonstration of precolostral antibodies. No vaccines are available. Inactivated BVD virus vaccines are sometimes used in sheep, but their effectiveness is unproved. (See also p 622.)

Cache Valley Virus: Cache Valley virus is a mosquito-transmitted cause of infertility, abortions, stillbirths, and multiple congenital abnormalities in sheep. The virus is endemic in most parts of the USA, Canada, and Mexico. Often, there are epizootics affecting sheep over a wide geographic area that can include several states. The most noticeable effects are stillborn lambs and the birth of live lambs with congenital abnormalities affecting the CNS and musculoskeletal system. Hydranencephaly, hydrocephalus, cerebral and cerebellar hypoplasia, arthrogryposis, scoliosis, torticollis, and hypoplasia of skeletal muscles are common. Infection before 32 days of pregnancy results in early embryonic death. Infection between 32 and 37 days of pregnancy results in musculoskeletal and CNS lesions. Infection between 37 and 48 days results in primarily musculoskeletal lesions. At the time of abortion or birth, the virus is usually no longer viable, and diagnosis is by demonstration of antibodies in precolostral serum or body fluids. Vaccines are not available.

Toxoplasmosis: *Toxoplasma gondii* is a major cause of abortion in small ruminants throughout the world. Ingestion of sporulated coccidian oocytes early in gestation results in resorption or mummification; if ewes contract the disease late in gestation, abortions or perinatal deaths occur. Ewes do not usually appear sick. In an outbreak, there is usually a wide range in gestational age of aborted fetuses. In most cases there are no gross lesions, but in a few cases there are distinct, small, white foci,

1–3 mm in diameter, in some cotyledons. The fetal brain often has focal areas of nonsuppurative inflammation on histology. Fetal serology (indirect hemagglutination inhibition, latex agglutination, or fluorescent antibody) may also be used. Once infected, ewes are immune, so running unbred ewes with aborting ones may allow them to develop immunity. Transplacental transmission is possible. Preventing contamination of feed by cat feces may help reduce exposure. Toxoplasmosis is a zoonosis. (See also p 685.)

Listeriosis: Abortion caused by *Listeria monocytogenes* in ewes usually occurs in late gestation. Abortng ewes show variable clinical signs, including fever, depression, and anorexia, and some may succumb to septicemia. There is some necrosis of cotyledons and the intercotyledonary areas, and the fetus is usually autolyzed. Mummification is possible. The fetal liver (and possibly lung) may have necrotic foci, 0.5–1 mm in diameter. Diagnosis is by culture. (See also p 656.)

Brucellosis: The major importance of *Brucella ovis* is as a cause of contagious epididymitis in rams. On a flock basis, brucellosis results in infertility, but it also causes late-term abortions, stillbirths, and birth of weak lambs. *B melitensis* is rare in the USA but causes abortion in areas where it is found. *B abortus* occasionally causes abortion in sheep. *Brucella* abortions occur late in gestation, resulting in placentitis with edema and necrosis of the cotyledons and thickened, leathery intercotyledonary areas. Many fetuses aborted due to *B ovis* are alive at the beginning of parturition, although fetuses can be mummified or autolyzed. Most fetuses aborted due to *B melitensis* or *B abortus* are autolytic. Culture of the placenta, abomasal contents, and the dam's vaginal discharge are diagnostic. A vaccine for *B melitensis* is available in some countries. *B melitensis* and *B abortus* are zoonotic. (See also p 1348.)

Salmonellosis: *Salmonella Abortusovis*, *S Dublin*, *S Typhimurium*, and *S Arizona* have caused abortions in sheep. *S Abortusovis* is endemic in England and Europe but has not been reported in the USA. The other serotypes occur worldwide. Most ewes are sick and febrile before aborting. There are no specific placental lesions, and the fetus is autolyzed. Diagnosis is by culture of placenta, fetus, or uterine discharge. *Salmonella* spp are zoonotic. (See also p 195.)

Bluetongue: Bluetongue virus infection is a cause of abortion, fetal mummification, stillbirth, and congenital brain malformation in lambs. The clinical syndrome, serotypes involved, and diagnosis are the same as for cattle (see p 1337). Most, if not all, reproductive failure is caused by attenuated vaccine viruses rather than field viruses. Serotype 8 bluetongue virus has been documented as a cause of abortions and congenital brain malformations in cattle in northwestern Europe, and this is widely regarded as the first confirmed outbreak of transplacental transmission of wild-type bluetongue virus in ruminants. Published studies from Europe have not found evidence that serotype 8 is a significant cause of fetal infection in sheep. However, there are a few anecdotal reports of abortions and congenital anomalies in sheep attributed to serotype 8, and experimentally the virus has been demonstrated to be capable of crossing the ovine placenta. The virus should be considered a potential problem in sheep until more is known.

Control of bluetongue is by management procedures to reduce exposure to biting midges and vaccination. Inactivated and modified-live vaccines are available and widely used, but the availability of each varies between countries. Modified-live vaccines are predominantly used in regions with a long history of bluetongue, such as the USA and Africa, but their use is controversial. If used, the vaccine should not be given to pregnant ewes. Also, the vaccine should not be given when *Culicoides* spp are active, because they can and do transmit the vaccine virus to unvaccinated animals, including pregnant females. Bluetongue virus has a segmented genome, and reassortment viruses are readily produced in animals simultaneously infected or vaccinated with more than one serotype. (See also p 738.)

Other Causes of Abortion: Akabane virus (where present) causes abortion and congenital anomalies in sheep and is a differential diagnosis for Cache Valley virus infection. *Coxiella burnetii* causes occasional abortion storms in sheep, with the clinical syndrome and fetal pathology the same as for goats (see below). *Neospora caninum* has been reported to cause occasional abortions in sheep, with the lesions resembling those of *Toxoplasma gondii*. Fungal placentitis also occurs but is not as common in sheep as in cattle or horses. Other organisms associated with sheep abortion include *Schnallenberg*

virus, Rift Valley fever, Nairobi sheep disease virus, Wesselsbron disease virus, *Francisella tularensis*, and *Leptospira* sp.

ABORTION IN GOATS

See also MANAGEMENT OF REPRODUCTION: GOATS, p 2182.

Noninfectious causes of abortion in goats include plant toxins, such as broomweed or locoweed poisoning; dietary deficiencies of copper, selenium, vitamin A, or magnesium; and certain drugs such as estrogen, glucocorticoids, phenothiazine, carbon tetrachloride, or levamisole (in late gestation).

Major infectious causes of abortion in goats are chlamydiosis, toxoplasmosis, leptospirosis, brucellosis, *Coxiella burnetii*, and listeriosis. *Campylobacter* causes abortions but is not nearly as important in does as in ewes.

Chlamydiosis (Enzootic Abortion):

Chlamydia abortus (the agent of enzootic abortion of ewes) is the most common cause of abortion in goats in the USA. In naive herds, up to 60% of pregnant does can abort or give birth to stillborn or weak kids. Abortions can occur at any stage of pregnancy, but most are in the last month. Reproductive failure is usually the only sign of *C. abortus* infection, but occasionally there is concurrent respiratory disease, polyarthritis, conjunctivitis, and retained placentas in the flock. Aborted lambs are usually fresh with no gross pathology. Placentitis is usually present and consists of reddish brown exudate covering cotyledons and intercotyledonary areas. Microscopically, necrotizing vasculitis and neutrophilic inflammation are present in the placenta. Chlamydial organisms can be visualized in appropriately stained placental smears, but they cannot be differentiated from *Coxiella burnetii*. Fluorescent antibody or immunohistochemical staining, ELISA, PCR, or culture can be used to definitively identify *C. abortus*. The placenta is the specimen of choice, but sometimes the diagnosis can be made by testing liver, lung, and spleen.

During an outbreak, aborting does should be isolated, and tetracyclines given orally or parentally. There is no chlamydial vaccine for goats, but the vaccine for sheep is relatively effective. Like sheep, goats that abort are immune. Sheep that abort due to *C. abortus* remain infected for years, if not life, and shed the organism during ovulation; whether this occurs in goats is not known. *C. abortus* is zoonotic, occasionally causing serious disease in pregnant women.

Toxoplasmosis: Toxoplasmosis is a common cause of abortion in goats in the USA, and toxoplasmal abortion in goats is similar to the syndrome in ewes. (See also p 685.)

Leptospirosis: The most common serovars of *Leptospira interrogans* involved in caprine abortion are Grippotyphosa and Pomona. Although sheep are relatively resistant to leptospirosis, goats are susceptible, with abortions occurring at the time of leptospiremia. Some does have anemia, icterus, and hemoglobinemia; others are afebrile and are not icteric. Diagnosis is by serology or identification of *Leptospira* spp in the dam's urine, the placenta, or fetal kidney. (See also p 646.)

Brucellosis: *Brucella melitensis* is the principal organism involved in abortions in animals with brucellosis; *B. abortus* is occasionally involved. Abortion may be accompanied by mastitis and lameness and is most common in the fourth month. The placenta is grossly normal, but does may develop chronic uterine lesions. Infection in adults is lifelong, with organisms shed in the milk (*B. melitensis* is zoonotic but rare in the USA). In the USA, control is by test and slaughter. Tube agglutination and card tests can be used as screening tests. (See also p 1348.)

Coxiella burnetii infection: *Coxiella burnetii* is increasingly recognized as an important cause of caprine abortion. Occasional outbreaks also occur in sheep. Late-term abortions, stillbirths, and weak lambs are the common presentations. Up to 50% of the flock may be involved. The placenta is covered by gray-brown exudate and the intercotyledonary areas are thickened. Microscopically, there is a necrotizing vasculitis in the placenta, and many chorionic epithelial cells are distended by small, coccobacillary organisms <1 µm in diameter. Infection involves only the placenta; without it, the diagnosis usually cannot be made. Diagnosis is by identification of *C. burnetii* by immunologic staining methods, PCR, or by isolation. *Coxiella* is zoonotic, causing Q fever in people. (See also p 623.)

Listeriosis: *Listeria monocytogenes* is a common pathogen in goats and causes sporadic abortions. There are no specific fetal lesions, and the fetus is often autolyzed. Does usually show no signs before abortion but may develop severe metritis after abortion. Diagnosis is by

isolation from the placenta, abomasal contents, or uterine discharge. In the rare case of a herd outbreak, preventive treatment with tetracycline is recommended. (See also p 656.)

Caprine Herpesvirus 1 (CpHV 1):

CpHV 1 is closely related to infectious bovine rhinotracheitis virus of cattle and causes sporadic outbreaks of late-term abortions often unassociated with other clinical signs. The virus also causes vulvovaginitis, balanoposthitis, and respiratory disease in adult goats and enteric and systemic diseases in neonatal goats. Fetuses can be fresh or autolyzed and do not contain diagnostic gross lesions. Presumptive diagnosis is by microscopic identification of necrosis with the presence of intranuclear inclusion bodies in the liver, lungs, and other organs. Definitive diagnosis is by identification of CpHV 1 by isolation, PCR, or immunologic staining methods. Not all fetuses contain lesions or virus, so multiple fetuses should be submitted. Infected goats can become latently infected and can shed the virus during times of stress. Vaccines are not commercially available in the USA.

ABORTION IN PIGS

See also MANAGEMENT OF REPRODUCTION: PIGS, p 2201.

Many agents that cause reproductive failure in sows produce a broad spectrum of sequelae, including abortions and weak neonates, as well as stillbirth, mummification, embryonic death, and infertility. Mummification is seen more frequently in swine than in many other species because of the large litter size. If only a few fetuses die, abortion rarely occurs; instead, mummies are delivered at term, along with live piglets or stillbirths.

Noninfectious Causes

High ambient temperature ($>32^{\circ}\text{C}$ [$>89.6^{\circ}\text{F}$]) is associated with increased returns to estrus, increased embryonic mortality, decreased farrowing rates, and small litters. The effect is greatest if heat stress occurs at the time of breeding or implantation. Increased embryonic mortality and increased irregular return to estrus are seen in pigs bred during the summer. High ambient temperature may play a role, but there is evidence that seasonal low progesterone levels are a major factor.

The estrogenic mycotoxins zearalenone and zearalenol interfere with conception

and implantation, causing infertility, embryonic death, and reduced litter size, but rarely, if ever, abortion. Another class of mycotoxins, the fumonisins, causes acute pulmonary edema in swine; sows that recover from the acute disease often abort 2–3 days later.

Other toxic causes of abortions or stillborn pigs include cresol sprays (used for mange and louse control), dicumarol, and nitrates. Nutritional causes of reproductive failure are not well defined. Vitamin A deficiency can cause congenital anomalies and possibly abortions. Riboflavin deficiency can cause early premature births (14–16 days), and calcium, iron, manganese, and iodine deficiencies have been associated with stillbirths and weak pigs.

Carbon monoxide toxicity due to faulty propane heaters has been associated with increased numbers of stillbirths and autolyzed full-term fetuses. Fetal tissues are cherry red; the sows do not appear affected.

Infectious Causes

The major infectious causes of reproductive failure in pigs include porcine reproductive and respiratory syndrome virus, porcine parvovirus, pseudorabies virus, Japanese B encephalitis virus, classical swine fever virus, *Leptospira* spp, and *Brucella suis*.

Porcine Reproductive and Respiratory Syndrome (PRRS):

PRRS is caused by an arterivirus. It is of major importance in the USA and throughout most of the world. Most PRRS strains do not cross the placenta until after 90 days of gestation. Consequently, most abortions are near the end of gestation. Affected litters contain fresh and autolyzed dead pigs, weak infected pigs, and healthy, uninfected pigs that often develop respiratory disease within a few days of birth. The sows are often anorectic and feverish a few days before aborting. Concurrent respiratory disease and increased numbers of bacterial infections in the herd are common. Hemorrhage in the umbilical cord, when present, is the only gross lesion associated with PRRS abortions. Not all fetuses are infected, so multiple fetuses should be sampled. Viral antigen is most consistently present in the fetal thymus and in fluid collected from the fetal thoracic cavity. PCR testing of pooled thoracic fluid from three to five fetuses is the most reliable means of diagnosis. Herd management is important in control and prevention. Inactivated and modified-live virus vaccines are available. (See also p 729.)

Porcine Parvovirus: Porcine parvovirus is ubiquitous in pigs in the USA and most of the world. Almost all females are naturally infected before their second pregnancy, and immunity is lifelong. Consequently, it is a disease of first-parity pigs. Gilts that are immunologically naive or have high passive antibody titers have the highest risk of reproductive disorders caused by the virus. Infection before day 30 of pregnancy results in early embryonic loss. Fetal infection between 30 and 70 days of gestation can result in death of the fetus and sometimes mummification. Not all fetuses are infected at the same time, and death at different stages of pregnancy is typical. Some fetuses survive and are born alive but persistently infected. Most fetuses infected after 70 days of gestation mount an immune response, clear the virus, and are healthy at birth. Litters with dead fetuses of varying sizes, including mummified fetuses, along with stillborn and healthy pigs born to first-parity gilts, are the hallmark of porcine parvovirus. Diagnosis is by fluorescent antibody testing, virus isolation using lung from mummified fetuses, or demonstration of precolostral antibody in stillborn pigs. Boars shed virus by varying routes, including semen, for a couple of weeks after acute infection and can introduce the virus into a herd. Effective inactivated vaccines are available.

Pseudorabies (Aujeszky Disease, Porcine Herpesvirus 1 Infection):

Pseudorabies is a cause of CNS and respiratory diseases. Infection results in latency, and seropositive animals are considered infected. Infection early in pregnancy can result in embryonic death and resorption of the fetuses. Infection later in pregnancy can result in abortion and birth of stillborn and weak pigs. Mummification can occur but is uncommon. There are no gross lesions in most aborted pigs, but a few have pinpoint white foci of necrosis in the liver and tonsils. Diagnosis is by virus isolation, PCR, or fluorescent antibody staining. Effective gene-deleted vaccines that allow serologic differentiation of vaccinated and naturally infected pigs were developed for the eradication program in the USA, but after eradication from commercial pigs was completed in 2003, vaccination was discontinued. Feral pigs in multiple states harbor the virus, and since 2003 there have been sporadic outbreaks of pseudorabies in herds that have contact with feral pigs. These outbreaks are currently controlled by herd depopulation. (See also p 1300.)

Japanese B Encephalitis Virus

Infection: Japanese B encephalitis is an arthropod-borne disease that causes reproductive failure in pigs and encephalitis in people. The disease is reported primarily in southeast Asia, Indian subcontinent, Indonesia, and Australasian regions. Infected litters can contain dead pigs of various sizes (including mummies), stillborn pigs, weak pigs, and pigs with CNS signs. Hydrocephalus and subcutaneous edema are the most common gross lesions. Diagnosis is confirmed by viral isolation and immunohistochemistry. Viral nucleic acid can be detected in tissue and blood samples using RT-PCR or nested RT-PCR. Pigs are the primary amplifying host for the virus and are vaccinated not only to prevent reproductive failure but also to prevent human infection.

Classical Swine Fever (Hog Cholera):

Classical swine fever is caused by a pestivirus eradicated from the USA but still a serious problem throughout much of the world. With highly virulent strains that cause serious maternal illness, abortion is common. With strains of moderate or low virulence, birth of mummified and stillborn pigs, weak pigs, and persistently infected pigs are more common. Fluorescent antibody staining, virus isolation, and PCR are used for diagnosis. Both killed and modified-live vaccines are available, but their use in the USA is prohibited. (See also p 713.)

Porcine Circovirus Infection:

Porcine circovirus type 2 (PCV2) is found worldwide, is ubiquitous in pigs, and is associated with several conditions, including sporadic outbreaks of late-term abortions and term litters with increased numbers of dead piglets. The dead piglets vary from small, mummified fetuses to stillbirths. Nonmummified fetuses typically have a large amount of serosanguineous fluid in their body cavities. Microscopically, there is myocardial necrosis and/or fibrosis, and PCV2 is present in the heart and other tissues. The incidence of PCV2 reproductive failure is very low; when it occurs the problem soon disappears, perhaps because most pigs are naturally exposed and immune before being bred. Diagnosis is based on presence of PCV2 DNA or antigen in precolostral serum samples from live born piglets. Immunohistochemistry and in situ hybridization are considered the gold standard to detect the agent. Vaccines are available for grower and finisher pigs, but their efficacy in preventing reproductive failure is unknown.

Leptospirosis: *Leptospira interrogans* (especially serovar Pomona) is a major cause of reproductive failure in swine (infertility, abortion, stillbirths, and the birth of weak piglets). Although acute leptospirosis occurs in adult swine, most cases are asymptomatic. Pigs infected with serovars Pomona and Bratislava can become chronic renal carriers. Abortion occurs 1–4 wk after infection, so the abortuses are autolyzed. Mummification, maceration, stillbirths, and weak pigs are also seen. Diagnosis is based on demonstration of leptospirae in fetal tissues or stomach contents. However, severely autolyzed fetuses may result in poor fluorescent antibody and immunohistochemistry results. PCR testing has better sensitivity and specificity. Vaccination with a multivalent bacterin every 6 mo helps prevent the disease. Streptomycin was formerly used to eliminate the carrier state and to treat pregnant sows during an outbreak, but it is no longer available for use in food animals. Experimentally, high levels of injectable oxytetracycline, tylosin, and erythromycin and high levels of tetracyclines in the feed have eliminated the carrier state. However, field results indicate that *Leptospira* infection cannot be reliably eliminated with antibiotics. Leptospirosis is zoonotic. (See also p 646.)

Brucellosis: *Brucella suis* infection in commercial swine has become rare in the USA as a result of state and federal control programs. However, it is present in feral pigs in multiple states; these represent a source of infection for commercial pigs and people. The route of infection is oral in most cases, but venereal transmission is not uncommon. Infected sows can abort at any stage of gestation, and abortions are not always accompanied by illness. Abortion is probably due to endometritis and fetal infection. There are few fetal or placental lesions, although some fetuses may be autolyzed. Diagnosis is by serology and isolation from the placenta and fetal tissues. No treatment has been uniformly effective. Control is based on test and slaughter. Brucellosis is one of the few venereal diseases recognized in swine. *B. suis* causes a serious zoonotic disease. (See also p 1348.)

Other Infectious Causes of Abortion:

Pigs with foot-and-mouth disease (see p 629), African swine fever (see p 711), and swine influenza (see p 1470) often abort, but they and their herdmates also have clinical signs of those diseases. Enteroviruses and encephalomyocarditis virus have been

reported to cause fetal losses in pigs, but they are not considered economically important. Blue eye paramyxovirus is an important cause of abortion, stillbirths, and mummified fetuses in parts of Mexico. Bacteria that cause sporadic abortions include *Staphylococcus aureus*, *Streptococcus* spp, *Erysipelothrix rhusiopathiae*, *Salmonella* spp, *Pasteurella multocida*, *Trueperella* (*Arcanobacterium*) *pyogenes*, *Listeria monocytogenes*, and *Escherichia coli*.

ABORTION IN HORSES

See also MANAGEMENT OF REPRODUCTION: HORSES, p 2187.

Noninfectious Causes

The most common noninfectious cause of abortion in horses is **twinning**. Most abortions related to twinning occur at 8–9 mo of gestation and may be preceded by premature lactation. Placental insufficiency ultimately causes abortion of twins.

Umbilical cord abnormalities, such as torsion due to abnormal length (>100 cm), are commonly diagnosed as a noninfectious cause of abortion, particularly in Thoroughbreds. Diagnosis of abortion due to cord torsion requires evidence of localized swelling or hemorrhage, because torsions occur in some normal births. Signs of fetal circulatory disturbances, such as subcutaneous edema, a swollen, soft liver, and microscopic mineralization of placental vessels, are also signs of umbilical cord obstruction. Various congenital fetal abnormalities have been reported in cases of noninfectious abortions.

Mare Reproductive Loss Syndrome:

In spring of 2001, horse farms in Kentucky and neighboring states experienced an explosive outbreak of early abortions and late-term abortions, stillbirths, and weak foals that died within a few days. Simultaneously there was a large increase in fibrinous pericarditis and unilateral uveitis in horses of all ages and both sexes. Together these conditions became known as mare reproductive loss syndrome (MRLS). Analysis of records showed that MRLS had occurred in the area in earlier years. MRLS has since been diagnosed in other states, including New York and Florida. An abortion storm with similar clinical signs and risk factors was recently reported from Australia.

Most early abortions occur at 40–80 days of gestation, with some losses occurring as late as 140 days. A few affected mares have colic, fever, and/or purulent vulvar

discharge, but most remain clinically normal. Typically, the first sign is abortion or finding a fetus dead in utero by ultrasound. Most fetuses are expelled within 2 days to 2 wk of dying and are autolytic. Neutrophilic placentitis and metritis are usually present. Most mares rebred during the same breeding season do not become pregnant, but conception is usually normal during the next breeding season. Late-term losses generally occur at 10 mo of gestation to term, and the mare usually does not display signs of impending parturition. Pathologic features of MRLS include the presence of amnionitis and funisitis, with only the amniotic portion of the umbilical cord affected. The placenta and umbilical cord are thickened, edematous, and discolored light brown to yellow. Neutrophilic inflammation of the umbilical cord and placenta are usually present, with the neutrophilic funisitis being characteristic of the syndrome. A variety of bacteria can be isolated from the fetuses, regardless of when they abort, but are not considered causative. Pasture exposure to eastern tent caterpillars (*Malacosoma americanum*) is an important risk factor, and both early and late-term abortions have been reproduced by oral administration of whole caterpillars or their exoskeletons but not their digestive tract. The mechanism causing abortion has not been confirmed. It has been proposed that an unidentified toxin associated with the exoskeleton of these caterpillars is involved, and that bacterial infections are secondary. Alternatively, caterpillar hairs (setae) may penetrate the oral or intestinal mucosa and carry bacteria, resulting in bacteremia with localization in the uterus and other organs. (The horses in the Australian outbreak were exposed to processionary caterpillars [*Ochragaster lunifer*]).

Prevention consists of pasture management to control the numbers of eastern tent caterpillars and other procedures to prevent exposure of pregnant mares to eastern tent caterpillars.

Fescue Grass Toxicosis: Ingestion of fescue infected by the endophyte *Neotyphodium coenophialum* causes prolonged gestation, agalactia, edema and premature separation of the placenta, and perinatal death. Abortion may occur in the last 2 mo of pregnancy due to severe edema and premature placental separation. The placenta is thickened and edematous and does not rupture normally at the cervical star. The chorioallantois precedes the foal through the birth canal instead of remaining attached to the uterus (red bag), resulting in anoxia and death of the fetus. The source of

the infected fescue can be pasture, hay, or bedding. (See also p 3016.)

Infectious Causes

Infectious causes of abortion include viral diseases (such as equine rhinopneumonitis and equine viral arteritis) as well as bacterial and fungal infections.

Equine Rhinopneumonitis (Equine Herpesvirus 1 Infection): Equine rhinopneumonitis, specifically equine herpesvirus 1 (EHV-1) infection, is the most important viral cause of abortion in horses, although EHV-4 has also been isolated from some cases. The principal mode of transmission of the virus from horse to horse is by direct contact through nasal secretions, reproductive tract discharge, placenta, or the aborted fetus. Short-distance airborne spread of infection is possible. Abortion is usually after 7 mo of gestation and is not preceded by maternal illness. The placenta may be edematous or normal. Gross fetal lesions include subcutaneous edema, jaundice, increased volume of thoracic fluid, and an enlarged liver with yellow-white lesions ~1 mm in diameter. Histologically, these lesions represent areas of necrosis containing intranuclear inclusions. Inclusion bodies are also found in necrotic lymphoid tissues. There is often a necrotizing bronchiolitis. Diagnosis is by fluorescent antibody, PCR, or virus isolation from fetal tissues. Prevention is based on vaccinating at 5, 7, and 9 mo of gestation as well as preventing exposure of pregnant mares to horses attending shows or other equine events. Abortion may occur despite regular vaccination. (See also p 1444.)

Equine Viral Arteritis (EVA): Abortion may follow clinical cases of EVA by 6–29 days. Abortion rates can approach 60% in a naive population as the result of direct impairment of placental function and severe fetal infection. Arteritis may be found in the fetal myocardium or placenta, but usually there are no fetal lesions. Stallions can be persistently infected, and EVA can spread venereally (via natural cover or insemination with shipped cooled or frozen semen) or by aerosol. Diagnosis is by a history of EVA shortly before abortion, virus isolation or PCR of placenta and/or fetal tissues, or by seroconversion of the dam. Prevention of EVA is by management to minimize viral transmission in breeding populations and to prevent development of carrier stallions. In the USA, a licensed modified-live virus vaccine is available for use in nonpregnant

mares. Antibody titers resulting from vaccination and natural infection cannot be differentiated, and the serologic status of horses can affect their import status. Therefore, the serologic status of breeding horses should be determined before vaccination, and all subsequent vaccinations should be recorded. (See also p 701.)

Bacterial Abortion: Bacterial placentitis is by far the most commonly diagnosed cause of abortion in many horse breeding areas. Placentitis is a significant cause of equine late-term abortion, premature delivery, and neonatal death. Except for *Leptospira* spp and nocardioform infections, most cases of bacterial placentitis are ascending. Ascending placentitis is characterized by premature udder development, increased uteroplacental thickness at the level of the cervical star, and mucopurulent vaginal discharge. If placentitis is untreated, placental function is compromised and placental separation ensues, resulting in fetal death and expulsion. In chronic placentitis, the fetus may show intrauterine growth retardation. *Streptococcus equi* subsp *zooepidemicus*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Enterobacter* spp, and *Klebsiella pneumoniae* are the most frequent isolates from the vaginal discharge, uterus, placenta, and fetal stomach contents. Other bacteria have also been reported to cause ascending placentitis in mares, including *Streptococcus equisimilis*, *Enterobacter agglomerans*, α -hemolytic streptococci, *Staphylococcus aureus*, and *Actinobacillus* spp. Examination of the placenta shows an edematous and thickened chorioallantois with fibrinonecrotic exudate at the level of the cervical star.

Leptospira spp placentitis is characterized by diffuse lesions secondary to hematogenous spread. Leptospiral

placentitis as a cause of abortion seems to be on the rise in Kentucky, Northern Ireland, England, and South America. Several serovars of *Leptospira interrogans* have been isolated from aborted equine fetuses (eg, Pomona, Grippotyphosa, Bratislava, Pomona type kennewicki, and Hardjo type hardjo-prajitno). In North America, the most common isolate is serovar Pomona type kennewicki, which is carried by several wildlife species, including the striped skunk, raccoon, whitetail deer, and opossum. Most leptospiral abortions occur between 6 and 9 mo of gestation. The placenta is thick, heavy, edematous, hemorrhagic, and occasionally covered with a brown mucoid material on the chorionic surface. Funisitis has also been described in leptospiral abortion. The fetus may have mild to moderate icterus and liver enlargement, and fetal histopathologic lesions may include various degrees of nephritis and hepatitis. Diagnosis is by fluorescent antibody staining of placenta or fetal kidney, liver, or lung and by fetal serology. (See also p 652.)

Nocardioform placentitis is a distinct type of equine placentitis first described in the USA in the late 1980s. Nocardioform placentitis may result in abortion, stillbirth, or birth of weak foals at term. Some mares may exhibit premature mammary gland development and lactation before abortion. Infection of the placenta is generally thought to be a sequela of hematogenous spread of microorganisms from a primary port of entry. The lesion is an extensive and severe exudative, mucopurulent, and necrotizing placentitis, frequently located at the base of the uterine horns or at the junction between the body and horns of the placenta. The affected area is thickened, and its chorionic surface is covered with brown, necrotic, mucopurulent exudate and dotted with white or yellow granular structures. Underneath this mucoid material, the chorionic surface is reddish white, mottled, and roughened. Villous necrosis and adenomatous hyperplasia of the allantoic epithelium, and hyperplasia with or without squamous metaplasia of the chorionic epithelium are frequently seen. Various groups of gram-positive, filamentous, branching bacteria have been implicated as etiologic agents in mares with nocardioform placentitis, including *Nocardia* spp, *Rhodococcus rubropertinctus*, *Amycolatopsis* spp, and *Crossiella equi*. The fetus is often severely underdeveloped as a result of placental insufficiency and does not show any remarkable gross or histologic lesions.

Ascending placentitis in a mare. Note the congested and thick cervical star area. Courtesy of Dr. Ahmed Tibary.

Potomac horse fever (see p 283), caused by *Ehrlichia risticii*, may be followed by abortion in mid- to late gestation. There is placentitis, and the placenta is often retained. *E. risticii* has been isolated from fetal lymphoid tissues after abortion. Histologically, there is fetal colitis. Identification of this colitis provides a presumptive diagnosis. There is a vaccine for Potomac horse fever, but its efficacy in preventing abortion is not known.

Equine Mycotic Placentitis: Mycotic placentitis in horses is also due to an ascending infection that causes placentitis with a thickened chorioallantois with variable exudate. Causative agents include *Aspergillus* spp, *Mucor* spp, *Candida* spp, *Histoplasma capsulatum*, *Coccidioides* spp, and *Cryptococcus neoformans*. Fetuses aborted in late gestation may be fresh, with evidence of growth retardation. A pale, enlarged liver or dermatitis may be found. Hyphae are found in the placenta, liver, lungs, or stomach contents.

ABORTION IN CAMELIDS

Pregnancy loss is a common complaint in camelid practice. The general approach to diagnosis is similar to that in other species. However, camelids have several unique features of placentation and pregnancy. In nearly all pregnancies, the fetal horn is the left uterine horn, and the placenta is epitheliochorial, microcotyledonary diffuse (such as in the horse), but the allantochorion adheres to the amniotic sac.

Noninfectious Causes

Noninfectious causes of abortion include fetal or placental abnormalities (twinning, umbilical cord torsion, severe deformities, chromosomal abnormalities and placental insufficiency, uterine torsion), luteal insufficiency (hypoluteidism), environmental stressors (severe disease process; long, stressful trip; heat stress), or iatrogenic causes (administration of prostaglandin $F_{2\alpha}$, corticosteroids, 8-way vaccines). Recurrent loss due to luteal insufficiency has been associated with obesity and possibly hypothyroidism. Presence of large avillous areas suggest placental insufficiency. Twin conceptions are not rare, and most are reduced to singleton or lost by day 45. Abortion of twins is generally seen between 5 and 9 mo of pregnancy.

On a herd basis, severe losses may be seen with nutritional deficiencies (selenium, vitamin A, iodine), or toxicosis (copper,

iodine). Lactating and very young maiden females may have an increased incidence of embryo and fetal losses.

Infectious Causes

Viruses: Viral causes of abortion are dominated by bovine viral diarrhea virus (BVDV). However, abortions due to equine herpesvirus 1, equine arteritis virus, and bluetongue virus have been reported. The most common BVDV serotype that affects alpacas and llamas is noncytopathic BVDV-1b. Abortion may occur at any stage of gestation, or a weak, persistently infected (PI) cria may be born prematurely. The birth of a PI animal can have significant effects on a herd of animals. Diagnosis of BVDV infection is based on virus isolation from fetal blood, fetal tissues (lymph nodes), and placenta. Immunohistochemistry may be performed on formalin-fixed tissues. PCR on whole blood samples is commonly used to screen newborn crias.

Bacteria: The most commonly diagnosed infectious causes of pregnancy losses are chlamydiosis and brucellosis (in some parts of the world). *Chlamydia* spp have been identified as a cause of abortion and birth of weak crias in llamas. *C. abortus* has been associated with infertility and ovarian hydrobursitis in camels.

Brucellosis (*Brucella abortus* and *B. melitensis*) is a common cause of abortion in camelids in some areas of the world.

Other reported bacterial causes of abortion in camelids include leptospirosis (*Leptospira interrogans* serogroups Icterohaemorrhagiae and Ballum), listeriosis (*Listeria monocytogenes*), and campylobacteriosis (*Campylobacter fetus fetus*). Coxiellosis (*Coxiella burnetii*) abortion is suspected to occur but has not been diagnosed definitively.

Nonspecific bacterial infections (*Escherichia coli*, *Streptococcus equi zooepidemicus*) are often isolated from cases of abortion that were due to placentitis.

Protozoa: Reported protozoal causes of abortion in camelids include toxoplasmosis (*Toxoplasma gondii*), neosporosis (*Neospora caninum*), and sarcocystosis (*Sarcocystis aucheniae* and *S. cruzi*). Trichomoniasis (*Trichomonas foetus*) has been isolated from camels, but there is no strong evidence it is involved in abortion.

Fungi: Sporadic cases of abortion due to *Encephalitozoon cuniculi* and *Aspergillus* spp have been reported.

BOVINE GENITAL CAMPYLOBACTERIOSIS

Bovine genital campylobacteriosis is a venereal disease of cattle characterized primarily by early embryonic death, infertility, a protracted calving season, and occasionally abortion. Distribution is probably worldwide.

Etiology and Epidemiology: The cause is the motile, gram-negative, curved or spiral, polar flagellated, microaerophilic bacteria *Campylobacter fetus venerealis* or *C. fetus fetus*. For many years, it was thought that *C. fetus fetus* was generally an intestinal organism, only occasionally caused abortion in cattle, and was not a cause of infertility. However, *C. fetus fetus* can also be a significant cause of the classic infertility syndrome usually attributed to *C. fetus venerealis*. There are several strains of *C. fetus fetus*, and the only way to determine whether a strain is a cause of infertility is to test that possibility in a group of heifers. *Campylobacter* spp are very labile and are destroyed quickly by heating, drying, and exposure to the atmosphere. Unless cultured quickly after collection from the animal and grown under microaerophilic or anaerobic conditions, *Campylobacter* spp will not grow.

C. fetus is transmitted venereally and also by contaminated instruments, bedding, or by artificial insemination using contaminated semen. Individual bulls vary in their susceptibility to infection; some become permanent carriers, while others appear to be resistant to infection. The primary factor associated with this variability seems to be the age-related depth of the preputial and penile epithelial crypts. In young bulls (<3–4 yr old), in which the crypts have not yet developed, infection tends to be transient, with transmission apparently relying on sexual contact with a noninfected cow within a matter of minutes to days after the initial breeding of an infected cow. Spontaneous clearance in these younger bulls does not seem to be related to any immune response, so reinfection can readily occur. In bulls >3–4 yr old, the deeper crypts may provide the proper microaerophilic environment required for chronic infections to establish.

In cows, the duration of the carrier state is also variable; some clear the infection rapidly, whereas others can carry *C. fetus* for ≥2 yr. IgA antibodies are shed in cervical

mucus in significant amounts in ~50% of cows for several months after infection and are useful diagnostically. Although most of the genital tract may be free of infection when a cow eventually conceives, the vagina may remain chronically infected throughout pregnancy.

Clinical Findings: Cows are systemically normal, but there is a variable degree of mucopurulent endometritis that causes early embryonic death, prolonged luteal phases, irregular estrous cycles, repeat breeding, and, as a result, protracted calving periods, assuming the breeding season is long enough to allow for complete clearance and a successful rebreeding. Observed abortions are not common. In herds not managed intensively, disease may be noticed only when pregnancy examinations reveal low or marginally low pregnancy rates but, more importantly, great variations in gestation lengths, especially when the disease has recently been introduced to the herd. In subsequent years, infertility is usually confined to replacement heifers and a few susceptible cows. Bulls are asymptomatic and produce normal semen.

Diagnosis: Campylobacteriosis and trichomoniasis (see p 1384) are similar syndromes, and investigations should be directed at both diseases. Systemic antibody responses are not helpful, because they are often due to nonpathogenic *Campylobacter* spp. A vaginal mucus agglutination test (VMAT) is useful, but because of variability in individual responses, at least 10% of the herd or at least 10 cows should be sampled. An ELISA test has been developed for use on vaginal mucus and is said to be more sensitive and able to detect a wider range of antibody responses than the VMAT. Vaginal culture immediately after abortion or infection can be used for diagnosis, but the number of organisms may be low; in addition, because *C. fetus* is labile and requires special techniques for isolation, success is limited.

An accurate diagnostic method is to test-breed heifers and then examine them for infection, but this is seldom practical. More often, the preputial cavity and fornix are either scraped and aspirated with an infusion pipette or infused with buffered

sterile saline, and the prepuce is massaged vigorously in the area of the fornx. The aspirate or sheath washing is then examined using a fluorescent antibody test and culture. *C. fetus* will survive for only 6–8 hr after collection, but inoculation into Clark's or similar media will allow survival for >48 hr. For maximum accuracy, bulls should be sampled twice, ~1 wk apart.

Caution should be exercised when *Campylobacter* spp are isolated from the placenta because of the possibility of contamination by nonpathogenic fecal *Campylobacter* spp. Conversely, failure to successfully isolate *C. fetus* from an infected aborted fetus or placenta often results from overgrowth of the colonies by contaminating organisms or the lethal effects of atmospheric oxygen.

Treatment and Control: Vaccination should start as soon as genital campylobacteriosis is diagnosed. Infected cows and cows at risk should be vaccinated. Vaccination of infected cows hastens the

elimination of *C. fetus* and, although cows may remain carriers, fertility is greatly improved. In routine use, the vaccine should be given once, ~4 wk before breeding starts; because antibody responses are short-lived, cows should be revaccinated halfway through the breeding season. Bulls are vaccinated for the same reason as cows (ie, for treatment as well as for prophylaxis) but are given twice the dose used for cows, 3 wk apart. The infection can also be eliminated in bulls by 1–2 treatments with streptomycin at 20 mg/kg, SC, together with 5 g of streptomycin in an oil-based suspension applied to the penis for 3 consecutive days.

For practical reasons, cows are not usually treated for genital campylobacteriosis. When practical, artificial insemination is an excellent way to prevent or control genital campylobacteriosis. Because *C. fetus* has been isolated from cows for >6 mo after the end of pregnancy, it has been suggested that artificial insemination should continue until all the cows in a herd have been through at least two pregnancies.

BRUCELLOSIS IN LARGE ANIMALS

Brucellosis is caused by bacteria of the genus *Brucella* and is characterized by abortion, retained placenta, and to a lesser extent, orchitis and infection of the accessory sex glands in males. The disease is prevalent in most countries of the world. It primarily affects cattle, buffalo, bison, pigs, sheep, goats, dogs (see p 1402), elk, and occasionally horses. The disease in people, sometimes referred to as undulant fever, is a serious public health problem, especially when caused by *B. melitensis*.

BRUCELLOSIS IN CATTLE

(Contagious abortion, Bang's disease)

Etiology and Epidemiology: The disease in cattle, water buffalo, and bison is caused almost exclusively by *Brucella abortus*; however, *B. suis* occasionally is isolated from seropositive cows but does not appear to cause clinical signs and is not contagious from cow to cow. In some countries, the disease in cattle is caused by *B. melitensis*. The syndrome is similar to

that caused by *B. abortus*. *B. melitensis* is not present in the USA.

Infection spreads rapidly and causes many abortions in unvaccinated cattle. In a herd in which disease is endemic, an infected cow typically aborts only once after exposure; subsequent gestations and lactations appear normal. After exposure, cattle become bacteremic for a short period and develop agglutinins and other antibodies; some cattle resist infection, and a small percentage of infected cows spontaneously recover. A positive serum agglutination test usually precedes an abortion or a normal parturition but may be delayed in ~15% of cows. The incubation period may be variable and is inversely related to stage of gestation at time of exposure. Organisms are shed in milk and uterine discharges, and the cow may become temporarily infertile. Bacteria may be found in the uterus during pregnancy, uterine involution, and infrequently, for a prolonged time in the nonpregnant uterus. Shedding from the vagina largely disappears with the cessation of fluids after parturition. Some infected cows that previously aborted

shed brucellae from the uterus at subsequent normal parturitions. Organisms are shed in milk for a variable length of time—in most cattle for life. *B. abortus* can frequently be isolated from secretions of nonlactating udders.

Natural transmission occurs by ingestion of organisms, which are present in large numbers in aborted fetuses, fetal membranes, and uterine discharges. Cattle may ingest contaminated feed and water or may lick contaminated genitals of other animals. Venereal transmission by infected bulls to susceptible cows appears to be rare. Transmission may occur by artificial insemination when *Brucella*-contaminated semen is deposited in the uterus but, reportedly, not when deposited in the midcervix. Brucellae may enter the body through mucous membranes, conjunctivae, wounds, or intact skin in both people and animals.

Brucellae have been recovered from fetuses and from manure that has remained in a cool environment for >2 mo. Exposure to direct sunlight kills the organisms within a few hours.

Clinical Findings: Abortion is the most obvious manifestation. Infections may also cause stillborn or weak calves, retained placentas, and reduced milk yield. Usually, general health is not impaired in uncomplicated abortions.

Seminal vesicles, ampullae, testicles, and epididymides may be infected in bulls; therefore, organisms are present in the semen. Agglutinins may be demonstrated in seminal plasma from infected bulls. Testicular abscesses may occur. Longstanding infections may result in arthritic joints in some cattle.

Diagnosis: Diagnosis is based on bacteriology or serology. *B. abortus* can be recovered from the placenta but more conveniently in pure culture from the stomach and lungs of an aborted fetus. Most cows cease shedding organisms from the genital tract when uterine involution is complete. Foci of infection remain in some parts of the reticuloendothelial system, especially supramammary lymph nodes, and in the udder. Udder secretions are the preferred specimens for culture from a live cow.

Serum agglutination tests have been the standard diagnostic method. Agglutination tests may also detect antibodies in milk, whey, and semen. An ELISA has been developed to detect antibodies in milk and serum. When the standard plate or tube serum agglutination test is used, complete agglutination at dilutions of 1:100 or more in

serum samples of nonvaccinated animals, and of 1:200 of animals vaccinated at 4–12 mo of age, are considered positive, and the animals are classified as reactors. Other tests that may be used are complement fixation, rivanol precipitation, and acidified antigen procedures.

Screening Tests: In official eradication programs on an area basis, the *Brucella* milk ring test (BRT) has effectively located infected dairy herds, but there are many false-positive tests. The brucellosis status of dairy herds in any area can be monitored by implementing the BRT at 3- to 4-mo intervals. Milk samples from individual herds are collected at the farm or milk processing plant. Cows in herds with a positive BRT are individually blood tested, and seropositive cows are slaughtered to determine herd status.

Nondairy and dairy herds in an area may also be screened for brucellosis by testing serum samples collected from cattle destined for slaughter or replacements through intermediate and terminal markets, or at abattoirs. Reactors are traced to the herd of origin, and the herd is tested. The cost of identifying reactors by this method is minimal compared with that of testing cattle in all herds. Screening tests, including the brucellosis card (or rose bengal) test and plate test, may be used in markets and laboratories to identify presumptively infected animals, thus reducing the number of more expensive and laborious diagnostic tests.

Brucellosis-free areas can be achieved and maintained, effectively and economically, by using the BRT on dairy herds and through market cattle testing. Adult cattle are sampled at the time of slaughter.

Supplemental tests using sensitive screening methods may be used in cattle in which the brucellosis status is unclear. Use of a battery of these tests improves the probability of detecting infected cattle that have remained in some herds as possible reservoirs of infection. Supplemental tests are also used to clarify the results of plate or card tests, especially in serum samples from vaccinated cattle. These tests, which include complement fixation and rivanol precipitation, are designed to detect primarily the antibodies specifically associated with *Brucella* infection. Another supplemental diagnostic procedure is to test milk samples from individual udder quarters by serial dilution BRT, which can be used to detect chronic infection in udders of cows that may have equivocal serum test reactions.

Control: Efforts are directed at detection and prevention, because no practical treatment is available. Eventual eradication depends on testing and eliminating reactors. The disease has been eradicated from many individual herds and areas by this method. Herds must be tested at regular intervals until two or three successive tests are negative.

Noninfected herds must be protected. The greatest danger is from replacement animals. Additions should be vaccinated calves or nonpregnant heifers. If pregnant or fresh cows are added, they should originate from brucellosis-free areas or herds and be seronegative. Replacements should be isolated for ~30 days and retested before being added to the herd.

Vaccination of calves with *B abortus* Strain 19 or RB51 increases resistance to infection. Resistance may not be complete, and some vaccinated calves may become infected, depending on severity of exposure. A small percentage of vaccinated calves develop antibodies to Strain 19 that may persist for years and can confuse diagnostic test results. To minimize this problem, calves in the USA are mostly vaccinated with a vaccine of Strain RB51. It is a rough attenuated strain and does not cause production of antibodies, which are detected by most serologic tests.

Whole-herd adult cattle vaccination using Strain 19 or RB51 has been practiced in certain high-incidence areas and selected herds in the USA with much success.

Vaccination as the sole means of disease control has been effective. Reduction in the number of reactors in a herd is directly related to the percentage of vaccinated animals. However, when proceeding from a control to an eradication program, a test and slaughter program becomes necessary. *B abortus* has been eradicated from cattle herds in the USA, and all states are considered free of brucellosis.

Brucellosis is endemic in some nondomesticated bison and elk herds in the USA. Transmission of *B abortus* to domestic cattle herds is rare but has occurred in several cattle herds commingling with infected elk in the greater Yellowstone Park area.

BRUCELLOSIS IN GOATS

The signs of brucellosis in goats are similar to those in cattle. The disease is prevalent in most countries where goats are a significant part of the animal industry, and milk is a common source of human brucellosis in many countries. The causal agent is *Brucella melitensis*. Infection occurs

primarily through ingestion of the organisms. The disease causes abortion at approximately the fourth month of pregnancy. Arthritis and orchitis may occur. Diagnosis is made by bacteriologic examination of milk or an aborted fetus or by serum agglutination tests. The disease can be eliminated by slaughter of the herd. In most countries where *B melitensis* is endemic, vaccination with the Rev. 1 strain is common. Rev. 1 is an attenuated strain of *B melitensis* and is administered by SC or intraconjunctival routes. *B melitensis* is highly pathogenic for people.

BRUCELLOSIS IN HORSES

Horses can be infected with *Brucella abortus* or *B suis*. Suppurative bursitis, most commonly recognized as fistulous withers or poll evil (see p 1064), is the most common condition associated with brucellosis in horses. Occasionally, abortion has been reported. It is unlikely that infected horses are a source of the disease for other horses, other animal species, or people. Brucellosis in horses is very rare in the USA because of elimination of the disease in cattle.

BRUCELLOSIS IN PIGS

Clinical manifestations of brucellosis in pigs vary but are similar to those seen in cattle and goats. Although the disease is often self-limiting, it remains in some herds for years. Brucellosis caused by *Brucella suis* rarely occurs in domestic animals other than pigs. Epidemics of brucellosis in people have been reported among packing-house workers, and the usual source is infected pigs. The prevalence in the USA is sometimes high among feral pigs. The incidence of swine brucellosis among domesticated animals in the USA is very low. Currently there are no known infected domestic swine herds.

Etiology and Transmission: *B suis* is usually spread mainly by ingestion of infected tissues or fluids. Infected boars may transmit the disease during service; the organism can be recovered from semen.

Pigs raised for breeding purposes are sources of infection. Suckling pigs may become infected from sows but most reach weaning age without becoming infected.

Clinical Findings: After exposure to *B suis*, pigs develop a bacteremia that may persist for as long as 90 days. During and after the bacteremia, localization may occur

in various tissues. Signs depend considerably on the site(s) of localization. Common manifestations are abortion, temporary or permanent sterility, orchitis, lameness, posterior paralysis, spondylitis, and occasionally metritis and abscess formation.

The incidence of abortion may be 0–80%. Abortions may also occur early in gestation and be undetected. Usually, sows or gilts that abort early in gestation return to estrus soon afterward and are rebred.

Sterility in sows, gilts, and boars is common and may be the only manifestation. Before attempting treatment for other diseases, it is logical to test for brucellosis in herds in which sterility is a problem. Sterility in sows is more frequently temporary but may be permanent. In boars, orchitis, usually unilateral, may occur, and fertility appears to be reduced.

Diagnosis: The principal means of diagnosis in pigs is the brucellosis card (rose bengal) test; however, other serum agglutination tests or complement fixation tests have been used. It is generally accepted that the tests have limitations in detecting brucellosis in individual pigs. Thus, entire herds or units of herds, rather than individual pigs, must be tested in any control program. Low agglutinin titers are seen in almost any size herd, regardless of infection status, and a few infected pigs may have no detectable titer. The card test is usually more accurate than conventional agglutination tests. Supplemental tests designed for cattle may also be used for pigs.

Prevention and Control: Caution should be practiced in the purchase of individual pigs that exhibit a low agglutinin titer unless the status of the entire herd of origin is known. Pigs should be isolated on return from fairs or shows before reentering the herd. Replacements should be purchased from herds known to be free of brucellosis, or they should be tested and isolated for 3 mo and retested before being added to the herd.

There is no vaccine for brucellosis in swine, and no practical recommendations can be made for treatment. Control is based on test and segregation as well as slaughter of infected breeding stock. Brucellosis remains a problem in feral swine and is a potential source of infection for domesticated herds and people.

BRUCELLOSIS IN SHEEP

Brucella melitensis infection in certain breeds of sheep causes clinical disease

similar to that in goats (see above). However, *B. ovis* produces a disease unique to sheep, in which epididymitis and orchitis impair fertility—the principal economic effect. Occasionally, placentitis and abortion are seen, and there may be perinatal mortality. The disease was first described in New Zealand and Australia and has since been reported from many sheep-raising areas of the world. *B. ovis* infection among sheep in the USA is rare.

There is no evidence that the disease is present in any other animal species. Rare natural and experimental infections in farmed red deer stags have been reported in New Zealand.

Rams as young as 8 wk have been infected experimentally by various nonvenereal routes. The disease can be transmitted among rams by direct contact. Active infection in ewes is unusual but has developed after mating with naturally infected rams. Contaminated pastures do not appear to be important in spread of the disease. Infection frequently persists in rams, and a high percentage shed *B. ovis* intermittently for several years.

Primary manifestations are lesions of the epididymis, tunica, and testis in rams; placentitis and abortion in ewes; and occasionally perinatal death in lambs. Lesions may develop rapidly. In rams, the first detectable abnormality may be a marked deterioration in semen quality associated with the presence of inflammatory cells and organisms. An acute systemic phase is rarely seen in naturally occurring infections. After regression of the acute phase—which may be so mild as to go unobserved—lesions may be palpated in the epididymis and scrotal tunics. Epididymal enlargement may be unilateral or bilateral. The tail of the epididymis is involved more frequently than the head or body, and the most prominent lesion is spermatoceles of variable size containing partially inspissated spermatic fluid. The tunics frequently become thickened and fibrous, and extensive adhesions develop between them. The testes may show fibrous atrophy; these lesions are usually permanent. In a few cases, palpable lesions are transient, while in others, organisms may be present in semen over long periods without clinically detectable lesions.

Because not all infected rams show palpable abnormalities of scrotal tissues (and not all cases of epididymitis are due to brucellosis), the remaining rams must be examined further. Rams shedding organisms, but having no lesions, must

be identified by culture of semen. Repeated examinations may be necessary to identify intermittent shedders. Microscopic examination of stained semen smears may also be helpful; fluorescent antibody examination is a highly specific diagnostic aid. Serologic tests used for eradication of disease and certification of animals include indirect ELISA, complement fixation, hemagglutination inhibition, indirect agglutination, and gel diffusion.

Incidence and spread of the disease may be reduced by regular examination of rams before the breeding season and culling of those with obvious genital abnormalities. Because susceptibility in rams increases markedly with age, it is advantageous to keep a young ram flock and isolate

noninfected rams from older, possibly infected rams.

Immunization of weaner rams with attenuated (Rev. 1) *B melitensis* has been recommended in some countries. Because infection in ewes apparently originates almost exclusively from service by infected rams, lamb losses through infection of ewes may be controlled economically by restricting vaccination to rams. There is no recommended vaccination in the USA.

Chlortetracycline and streptomycin used concurrently have effected bacteriologic cures. However, treatment is not economic except in especially valuable rams, and even if infection is eliminated, fertility may remain impaired.

CONTAGIOUS AGALACTIA

First recognized in Italy more than 200 years ago, contagious agalactia is primarily a disease of dairy sheep and goats and is characterized by an interstitial mastitis leading to a loss of milk production, arthritis, and infectious keratoconjunctivitis. It is more often seen on farms practicing traditional husbandry. Contagious agalactia is principally caused by the wall-less bacterium *Mycoplasma agalactiae*, but in recent years, *M mycoides capri* (*Mmc*; formerly known as LC), and, to a lesser extent, *M capricolum capricolum* (*Mcc*) and *M putrefaciens* have also been isolated from goats with mastitis, arthritis, and occasionally, respiratory disease. The clinical signs of these infections are sufficiently similar to those of contagious agalactia for the OIE to include them as causes of this listed disease.

Etiology and Epidemiology: Mycoplasmas that cause contagious agalactia can persist for >1 yr after clinical recovery of infected animals, which are the main reservoir of the organism. The introduction of such carriers into a susceptible flock can initially cause high morbidity and mortality. Once established in a herd, young ruminants become infected while suckling. Adults are contaminated via the milkers' hands, milking machines, or possibly by bedding. Other routes of transmission may include aerosols of infective exudates over

short distances and ingestion of contaminated water.

Sheep and goats are equally susceptible to *M agalactiae*, but goats are additionally susceptible to *Mcc*, *Mmc*, and *M putrefaciens*. However these mycoplasmas may be found in both animal species in regions where they graze together. In general, clinical disease is more pronounced in goats. Antibodies to *Mcc* and *Mmc* have been detected in South American camelids, but no mycoplasmas have yet been isolated. Because alpacas, llamas, and vicuñas develop polyarthritis, pneumonia, and pleuritis, it is likely that mycoplasmas may eventually be found. *Mmc* has also been isolated from cattle, although its role in disease in this species is not clear.

Contagious agalactia has been reported in many countries surrounding the Mediterranean, in particular Portugal, Spain, Greece, Italy, France, Turkey, Israel, and North Africa, as well as in many parts of the Middle East, most notably Iran, India, Mongolia, and parts of South America. Sporadic cases have been reported in the USA.

Clinical Findings and Lesions: The incubation period ranges from 1 wk to 2 mo and can be followed by either an acute disease with fever, neurologic signs, and occasionally death or, more commonly, a subacute or chronic disease characterized

by mastitis, arthritis, and infectious keratoconjunctivitis. The infection begins as an interstitial mastitis giving rise to a hot, swollen, and painful udder, followed by a sudden drop in the quantity and quality of milk production. The milk may appear discolored and granular, separating into watery and solid phases, or take on a thick, yellow consistency with milk clots obstructing the teat duct. After several days, the affected udder shrinks because of damage to secretory tissue. Abscesses within the udder and enlargement of the retromammary lymph nodes may also be seen. Generally the clinical condition improves after a few weeks, with partial restoration of udder function, but the quality of milk remains abnormal. In some cases, atrophy and fibrosis lead to permanent loss of milk production.

The acute syndrome may lead to abortion and weak lambs as a result of ingestion of infected milk or starvation brought about by reduced milk production. Arthritis can be seen in adults and the young who find it difficult to keep up with the flock; affected animals may be seen limping or sitting on their carpal joints because of the discomfort. In these animals, the joints are hot, swollen, and painful. Conjunctivitis presents as a discharge of clear exudates from the eyes, followed by corneal opacity, keratitis, purulent exudation, and occasionally ulceration and panophthalmitis. Severe cases may result in irreversible blindness. Necropsy often reveals generalized peritonitis among animals that die during the acute stage. The infected udder is grossly atrophic in either one or both halves. Microscopically, the chronic inflammatory reaction in the stroma shows increased fibrosis and a reduced number of glandular acini. Infected joint capsules are edematous, and the synovium may contain clumps of fibrin. Articular surfaces may be eroded and occasionally ankylosed. In early stages of keratitis, the cornea is edematous and infiltrated with leukocytes; later, abundant purulent exudate infiltrates both the cornea and the ciliary body.

M. putrefaciens is common in milking goat herds in western France. It can be isolated from the milk of animals with or without clinical signs, and milk production is usually severely affected. The milk of affected animals has a characteristic smell of putrefaction.

Diagnosis: When a flock is severely affected, clinical diagnosis is easy; the three major signs—mastitis, arthritis, and keratoconjunctivitis—are generally present,

although rarely in the same animal. However, an acute form, in which there is septicemia without specific local signs, can confound the diagnosis.

Laboratory diagnosis is the only means of confirmation. Preferred samples from living animals include milk and udder secretions, joint fluid from arthritic cases, eye swabs from cases of ocular disease, and serum for antibody detection. The ear canal is a rich source of pathogenic mycoplasmas. Isolation of mycoplasmas from the blood during the brief mycoplasmaemia stage of the disease is rarely successful. Samples from dead animals should include udder and associated lymph nodes, joint fluid, lung tissue (at the interface between diseased and healthy tissue), and pleural or pericardial fluid. Samples should be kept moist and cool and sent promptly to a diagnostic laboratory. PCR tests, which can be performed directly on clinical samples, including milk, can be used to confirm the diagnosis.

Identification of the organism is usually achieved by the growth inhibition or immunofluorescence tests using hyperimmune rabbit antiserum and, increasingly, by PCR tests that can be performed directly on clinical samples, including milk, within hours. PCR, together with denaturing gradient gel electrophoresis, which can detect all causative mycoplasmas in a single reaction, has been described.

Detection of antibodies in serum by ELISA provides rapid diagnosis of disease but may not be very sensitive in chronically affected herds and flocks. Indirect ELISA, some commercially available, have been used routinely in control programs to screen herds for *M. agalactiae* but less so for *M. mc* and *M. cc*. Immuno (Western) blotting can be used to confirm suspect ELISA results and can distinguish field infection from vaccine antibody. In areas believed to be free of contagious agalactia, it is usually necessary to isolate and identify the causative organism to confirm infection. Serological tests are not widely available for *M. putrefaciens*.

A number of other mycoplasmas such as *M. marginini*, *M. bovis*, and *M. conjunctivae* have occasionally been isolated from mastitic milk and joint fluids, but their role in disease is not known. *M. conjunctivae* is a common cause of keratoconjunctivitis but does not affect the udder or joints. Other bacteria causing mastitis include staphylococci, streptococci, *Escherichia coli*, and *Klebsiella*; caprine arthritic encephalomyelitis virus and *Erysipelothrix rhusiopathiae* should also be considered in cases of arthritis.

Treatment, Control, and Prevention:

Regular laboratory monitoring of flocks/herds and replacement animals may help to prevent spread or introduction of disease and can be done on serum and/or milk (including bulk tank milk) by serology, culture, or PCR. Culling or isolation of infected animals is generally advised, because udder damage is considered permanent. When this is not possible, hygienic measures, such as improved milking hygiene and pasteurizing milk before feeding to the young, should be implemented.

Antibiotics that inhibit cell wall synthesis (eg, penicillins) are not effective against contagious agalactia. In vitro tests have shown that strains of *M agalactiae* are still sensitive to fluoroquinolones and macrolides. These can bring about clinical improvement, particularly if given early in the disease, but there is always the danger of promoting carrier animals. Resistance to tetracyclines has been reported for some

strains of *M agalactiae*. The use of erythromycin and tylosin can destroy milk-producing tissue in small ruminants. In many disease-free countries and regions, a confirmed infected herd is always slaughtered.

In countries bordering the Mediterranean, both attenuated and inactivated vaccines have been used with mixed success. Some have provided protection from clinical disease and have been useful in endemic areas; however, they do not prevent transmission of the mycoplasmas. Generally, the duration of immunity, particularly to the formalinized, inactivated vaccines that are used in Europe, is short. Vaccines containing two or three of the causative agents are now available, but published data on their effectiveness is scarce.

Zoonotic Risk: There is no evidence that contagious agalactia is transmitted to people.

CYSTIC OVARY DISEASE

Among domestic animals, cystic ovary disease (COD) is most common in cattle, particularly the dairy breeds, but it occurs sporadically in dogs (see p 1395), cats, pigs, and perhaps mares.

Cystic Ovary Disease and the Corpus Luteum:

Three ovarian structures in cattle may include the term "cyst": follicular cysts, luteal cysts, and cystic corpus luteum (CL). However, in contrast to the other two, the structure sometimes described as a cystic CL (a CL with a cavity or "lacunae") actually arises after normal ovulation. CL with a lacunae are a normal stage or variation of CL development and are found in normally cycling and pregnant cows without concurrent abnormal reproductive performance. The lacunae can be compared with the homogeneous, liverlike consistency of the base of a typical CL.

The CL may have an ovulation crown or papilla at its apex; however, 10%–20% of functional, normal CL fail to develop this feature.

The two pathological forms of bovine cystic ovary disease, follicular cysts and luteal cysts, are etiologically and pathophysiologi-

cally related but differ clinically. Both are characterized by the presence of a fluid-filled structure >25 mm diameter, persisting for >7 days and associated with abnormal reproductive performance.

FOLLICULAR CYSTIC OVARY DISEASE

(Cystic follicles, "Bulling")

Follicular cystic ovary disease may be defined on a number of levels. Essentially, all signs relate to the disruption of the normal endocrine events of the estrous cycle, through the failure of ovulatory events. Key features include the presence of a thin-walled, fluid-filled structure >25 mm diameter and present for >7 days in the absence of a CL on ultrasonographic imaging of the ovary. Along with occasional behavioral signs of nymphomania, such as short inter-estrus intervals and excessive heat behavior, are endocrine changes, including a suboptimal luteinizing hormone (LH) surge and persistently increased estradiol levels.

Etiology and Pathogenesis:

A hereditary predisposition has been implicated in dairy cattle. Cystic ovary disease or syndrome (COD) is commonly considered to be associated with negative energy balance and stress factors in dairy cows that are high milk producers. Genetic predisposition to partition glucose to the udder to prioritize lactose synthesis and milk production is characterized by insulin resistance in Holstein cattle. IGF-1 is a cytokine associated with metabolic influences on reproduction and hence COD. Incidence increases with age. Most cases occur within 3–8 wk of parturition at the first attempted postpartum ovulation, coinciding with peak daily milk production and rapidly decreasing body condition. The reported herd incidence is 5%–25% per lactation, or higher in some problem herds.

During normal proestrus, regression of the CL coincides with development of a selected follicle, while the growth of any additional follicles is inhibited. In animals developing COD, ovulation fails to occur and the dominant follicle continues to enlarge. An important component of the etiology is the failure of positive feedback of follicular estrogen on the hypothalamus via estrogen receptor α to release sufficient GnRH during estrus to trigger an LH surge. The end result is a failure of ovulation at the time of estrus. Moreover, other follicles may grow and form multiple cysts either bilaterally or unilaterally.

Grossly, follicular cysts resemble enlarged follicles, generally defined as varying in size from 25 mm to 50–60 mm in diameter. The size and form of an affected ovary depends on the number and size of cysts present. The cystic ovary is capable, at least initially, of steroidogenesis, and its products vary from estrogens to progesterone to androgens. The actions of the various hormones produced or the absence of the stabilizing action of high progesterone from the normal CL during ~75% of the estrous cycle (or both) are responsible for the changes seen in the genital tract, body conformation, and general behavior.

Clinical Findings: Behavioral aberrations range from frequent, intermittent estrus with exaggerated monosexual drive to bull-like behavior, including mounting, pawing the ground, and bellowing. This behavior may be accompanied by masculinization of the head and neck. Relaxation of the vulva, perineum, and the large pelvic ligaments, which causes the tail head to be elevated, can occur in chronic cases. Some affected cows show these

signs, but others may be sexually quiescent; anestrus or subestrus cows are a common presentation.

The affected ovaries generally are enlarged and rounded, but their size varies, depending on the number and size of cysts. Their surface is smooth, elevated, and blister-like. Cysts frequently are multiple and may approach 4–6 cm in diameter. Under the influence of hormones produced by the cystic ovary or the lack of hormones (especially progesterone) normally present during estrous cycles, the uterus undergoes palpable changes, which in turn vary with the duration of the cystic condition. Thus, during the first week, the uterine wall is thickened and edematous as an extension of the preceding estrus. Toward the end of the first week, the uterine wall develops a sponge-like consistency. In chronic cases, atony and atrophy of the uterine wall are common. Occasionally, the uterine horns become markedly shortened. Some degree of mucoid to mucopurulent vaginal discharge is common. Hydrometra, a fluid-filled, extremely thin-walled uterus, is seen occasionally.

Diagnosis: Palpation of the uterus may help differentiate a follicular cyst from a dominant preovulatory follicle; the estrous cow has a coiled, extremely turgid uterus and a follicle. As noted earlier, cystic cows fail to ovulate a preovulatory follicle after undergoing CL regression and, on examination of the reproductive tract, they present with a large follicle, absence of a CL, and absence of a turgid uterus. Ultrasound technology per rectum can be used to differentiate cysts from corpora lutea and may help diagnose cyst type (ie, follicular cyst wall diameter has been described as <3 mm vs luteal cyst wall diameter >3 mm). Larger, multiple cysts are easily identified by rectal palpation. History, conformation, and uterine changes, when present, provide supplemental diagnostic evidence.

Treatment: COD may be frustratingly unresponsive to therapy. Some cysts respond readily to an LH-type hormonal treatment. In the past, human chorionic gonadotropin (hCG) was commonly used. It is most effective at 10,000 USP units IM, although success with lower doses given IM or IV has also been reported.

Hormone therapy with GnRH may be effective at 100 mcg and less antigenic than hCG. To hasten the onset of the first estrus after treatment, prostaglandin (PG) $F_{2\alpha}$ products can be given 7 days after hCG or

GnRH. Ovulation synchronization protocols combine GnRH and PGF₂α to control follicular dynamics, luteolysis, and ovulation. They allow for fixed timed artificial insemination (TAI) of cattle without the need for estrus detection and have been successfully used to treat cows with cystic ovaries. This protocol consists of giving GnRH, then prostaglandin 7 days later, then a second administration of GnRH 48 hr later, and finally TAI 0–24 hr later. Breeding on the first estrus may reduce recurrence by establishing pregnancy as soon as possible. However, COD recurrence is a risk.

Manual rupture is used, but the potential danger of traumatizing the ovary and causing hemorrhage with subsequent local adhesions should not be overlooked.

Prognosis: After therapy with an LH-type hormone, a normal, fertile estrus can be expected in 15–30 days. With GnRH therapy, 25% of cases required a second treatment, and 5% required a third. One-third of the cases treated for the third time did not respond. Spontaneous recovery is possible and is most common in cases arising during the first 50 days after calving. Likewise, successful treatment encourages perpetuation of the disease in the herd if the offspring are used for breeding. Although COD in cattle clearly has a genetic component, it is unlikely that a single farm using artificial insemination can significantly influence the incidence. In Sweden, progress has been made in reducing the condition through culling and selection procedures for bulls used in artificial insemination, but affected cows are often still treated.

LUTEAL CYSTIC OVARY DISEASE

Luteal cystic ovary disease is characterized by enlarged ovaries with one or more cysts, the walls of which are thicker than those of follicular cysts because of a lining of luteal tissue. Incidence ratios of follicular versus luteal cysts vary greatly because of diagnostic tendencies of individual veterinarians. Classically, luteal COD is defined as the presence of a fluid-filled ovarian structure >25 mm diameter persisting >7 days in the absence of a CL and with a wall diameter >3 mm, usually associated with abnormal reproductive signs. Normal lacunae formation in CL may be incorrectly classified as luteal COD.

Etiology and Pathogenesis: The basic causes of true luteal cysts are believed to be

the same as for follicular cysts. The release of luteinizing hormone (LH) may be somewhat greater than that occurring when follicular cysts develop, and sufficient to initiate luteinization of follicles but inadequate to cause ovulation. Luteal cysts may be an extension of follicular cysts such that the nonovulatory follicle is partially luteinized spontaneously or in response to hormonal therapy.

Clinical Findings: Luteal cysts are accompanied by normal conformation and anestrus behavior. Rectal palpation reveals a quiescent uterus characteristic of the luteal phase of the estrous cycle. Luteal cysts are recognized as smooth, fluctuant domes protruding above the surface of the ovary. Usually, they are single structures.

Luteal cysts are differentiated from follicular cysts on the basis of palpable characteristics of both the structure and the uterus and, to some extent, on the cow's behavior. Progesterone assay and ultrasonography can help differentiate between follicular and luteal cysts, although with either method a final diagnostic decision remains somewhat subjective. On attempts to manually rupture the cystic structure, follicular cysts burst or rupture under minimal pressure whereas luteal cysts cannot be ruptured with reasonable force. Both types of cysts respond to LH or GnRH therapy, but PGF₂α will lyse some luteal cysts and generally all diestrual CL structures.

Treatment and Control: The treatment of choice is luteolytic doses of PGF₂α if a correct diagnosis can be ascertained. A normal estrus is expected in 3–5 days. The major limitation of this treatment is the difficulty in accurately estimating the amount of luteal tissue present. If the structure being diagnosed as a luteal cyst is really a developing CL (as discussed above, sometimes called a cystic CL), it may not respond because dairy cows do not become highly responsive to the luteolytic action of PGF₂α until day 6 after estrus. Ultrasound examination is increasingly common and facilitates diagnosis of ovarian structures. Luteal cysts also respond to human chorionic gonadotropin and GnRH therapy that is effective in the treatment of follicular cysts, but the next estrus could occur 5–21 days after treatment. Manual rupture of luteal cysts is not recommended because of the risk of trauma and hemorrhage. Because of poor estrus detection practices on many dairy farms, the treatment of choice for both follicular and luteal cysts is intravaginal

progesterone/prostaglandin (a fixed timed artificial insemination protocol) (see p 1355). Application of this protocol in affected cows promotes timely breeding after treatment.

CYSTIC OVARY DISEASE AS A HERD PROBLEM

Individual herds may experience exceptionally high rates (~50%) of cystic ovary disease (COD) over a period of months. Determining the cause of these multifactorial episodes is not easy, but the following questions should be addressed: 1) Is the diagnosis accurate, ie, are the structures being identified as cysts really cysts? This can be established via second opinion diagnoses, determination of milk or plasma progesterone levels, ultrasound examination of the ovaries in suspected cases, observing ovarian changes and time of estrous activity after treatment with prostaglandin products, and/or improving diagnostic skills by continuing education. 2) Has the palpation examination schedule for the herd changed? Initiating routine postpartum examinations for all cows and increasing frequency of herd visits can result in an increased apparent incidence. 3) Has the herd incidence of periparturient complications and stress increased? Cows having problems around calving (such as twins, milk fever, dystocia, retained

placenta, ketosis, etc) are much more likely to develop cysts. Attempts to reduce these complications are indicated. 4) Have herd genetics been considered? It is well accepted that ovarian cysts are more common in certain lines. 5) Has the nutritional program of the herd been evaluated? Nutritional problems are frequently implicated as a risk factor for COD. Proper nutritional management of dairy herds is always warranted. Monitoring the effects of the nutritional program via a body condition scoring program should be done as part of the effort to reduce ovarian cysts in problem herds. 6) Has management of cows around estrus changed? Social and environmental changes may cause stresses associated with COD.

CYSTIC OVARY DISEASE IN MARES

When diagnosing the reproductive status of mares, it must be remembered that follicles during estrus are normally 4–6 cm in diameter. Ovulation failure can also be seen in mares having irregular estrous cycles during the spring or fall transition phases of the reproductive cycle, but this state is not treated in the same way as the cystic ovary disease condition of cattle. The granulosa cell tumor condition in mares causes marked enlargement of one ovary but differs from cystic ovary disease of cattle.

EQUINE COITAL EXANTHEMA

(Genital herpespox, Equine venereal balanitis in stallions)

Etiology and Epidemiology: Equine coital exantema is a benign venereal disease of horses that probably occurs worldwide. It affects both sexes and is caused by equine herpesvirus type 3 (EHV-3). This virus has a single antigenic type but also has small and large plaque variants in tissue culture, indicating that variation may occur in the severity of field outbreaks. Although the primary route of transmission is venereal, outbreaks have been documented in which transmission occurred via contaminated supplies and instruments or by the use of a single glove for rectal examination of many mares. It is probably for this reason that EHV-3 has also been isolated from horses that have not been bred.

Equine coital exantema is probably transmitted only in the acute phase of the disease; after the lesions have healed, horses do not appear to shed the virus. However, the existence of a carrier state is unclear: the scars that persist after healing may identify potential carriers, but such asymptomatic carriers have not been identified. Immunity is short-lived, but evidence from stallions shows that recurrence is not likely within a single breeding season.

Clinical Findings: Clinical signs in mares develop 4–8 days after sexual contact or veterinary examination and are manifest by the appearance of multiple, circular, red

nodules up to 2 mm in diameter on the vulvar and vaginal mucosa, the clitoral sinus, and perineal skin. These lesions develop into vesicles and then pustules and eventually rupture, leaving shallow, painful, ulcerated areas that may coalesce into larger lesions. Edema can develop in the perineum and may extend to between the thighs. Occasionally, ulcers will be found on the teats, lips, and nasal mucosa. Secondary bacterial infection of the ulcers by *Streptococcus* spp is common, causing the ulcers to enlarge and exude a mucopurulent discharge. In such cases, the horse may become febrile. Unless secondary bacterial infection occurs, skin healing is complete within 3 wk, but clitoral and vaginal ulcers heal more slowly. Skin lesions persist for long periods as unpigmented scars. However, pregnancy rates are not reduced.

Lesions in stallions are similar to those in mares and are found on both the penis and prepuce. As a result, intromission is painful, and the stallion may be reluctant to copulate. If copulation does occur during the ulcerative stage, the ulcers may hemorrhage into the ejaculate, reducing sperm viability.

Diagnosis: A tentative diagnosis is based on clinical signs and confirmed by identifying (using electron microscopy) the virus in cells from the margin of ulcers. Typical intranuclear herpesvirus inclusion bodies can also be seen in cytologic or histologic preparations. Acute and convalescent samples for serum neutralization or complement fixation tests can also be diagnostic, but these tests must be interpreted carefully because both EHV-1 and EHV-4 have also been isolated from genital lesions.

Treatment and Prevention: Sexual rest is essential to allow ulcers to heal and prevent spread of the disease. The use of antibiotic ointments to prevent secondary infections is also advisable. Affected horses should be isolated until all lesions have healed, and disposable equipment should be used for examinations. During the acute phase of the disease, mares should be bred only by artificial insemination. No vaccine is available. All horses should be examined carefully before they are allowed to breed, keeping in mind that the incubation period is up to 10 days.

MASTITIS IN LARGE ANIMALS

Mastitis, or inflammation of the mammary gland, is predominantly due to the effects of infection by bacterial pathogens, although mycotic or algal microbes play a role in some cases. Pathologic changes to milk-secreting epithelial cells from the inflammatory process often bring about a decrease in functional capacity. Depending on the pathogen, functional losses may continue into further lactations, which may reduce productivity and potential weight gain for suckling offspring. Although most infections result in relatively mild clinical or subclinical local inflammation, more severe cases can lead to agalactia or even profound systemic involvement, resulting in death. Mastitis has been reported in almost all domestic mammals and has a worldwide geographic distribution. Climatic conditions, seasonal variation, bedding, housing density of livestock populations, and husbandry practices may affect the incidence and etiology. However, it is of greatest frequency and economic importance in species that

primarily function as producers of milk for dairy products, particularly dairy cattle. (See also UDDER DISEASES, p 1385.)

MASTITIS IN CATTLE

Almost any microbe that can opportunistically invade tissue and cause infection can cause mastitis. However, most infections are caused by various species of streptococci, staphylococci, and gram-negative rods, especially lactose-fermenting organisms of enteric origin, commonly termed coliforms. From an epidemiologic standpoint, the primary sources of infection for most pathogens may be regarded as contagious or environmental.

Except for *Mycoplasma* spp, which may spread from cow to cow through aerosol transmission and invade the udder subsequent to bacteremia, contagious pathogens are spread during milking by milkers' hands or the liners of the milking unit. Species that use this mode of

transmission include *Staphylococcus aureus*, *Streptococcus agalactiae*, and *Corynebacterium bovis*. Most other species are opportunistic invaders from the cow's environment, although some other streptococci and staphylococci may also have a contagious component. Additionally, contagious transmission infrequently occurs for pathogens typically associated with environmental reservoirs, eg, through the development of host-adapted virulence factors (*Escherichia coli*) or by shedding of overwhelming numbers of bacteria from infected udders (*Trueperella* [formerly *Arcanobacterium*] *pyogenes*).

The bedding used to house cattle is the primary source of environmental pathogens, but contaminated teat dips, intramammary infusions, water used for udder preparation before milking, water ponds or mud holes, skin lesions, teat trauma, and flies have all been incriminated as sources of infection.

Intramammary infections are often described as subclinical or clinical mastitis. **Subclinical mastitis** is the presence of an infection without apparent signs of local inflammation or systemic involvement. Although transient episodes of abnormal milk or udder inflammation may appear, these infections are for the most part asymptomatic and, if the infection persists for at least 2 mo, are termed chronic. Once established, many of these infections persist for entire lactations or the life of the cow. Detection is best done by examination of milk for somatic cell counts (SCCs) (predominantly neutrophils) using either the California Mastitis Test or automated methods provided by dairy herd improvement organizations. SCCs are positively correlated with the presence of infection. Inflammatory changes and decreases in milk quality may start with SCCs as low as 100,000 cells/mL. Although variable (especially if determined on a single analysis), an SCC of $\geq 280,000$ cells/mL in a cow indicates a $>85\%$ chance of being infected. Likewise, the higher the SCC in a herd bulk tank, the higher the prevalence of infection in the herd. Herd SCCs $<200,000$ cells/mL are considered desirable, and lower counts can be attained. Causative agents must be identified by bacterial culture of milk.

Clinical mastitis is an inflammatory response to infection causing visibly abnormal milk (eg, color, fibrin clots). As the extent of the inflammation increases, changes in the udder (swelling, heat, pain, redness) may also be apparent. Clinical cases that include only local signs are

referred to as mild or moderate. If the inflammatory response includes systemic involvement (fever, anorexia, shock), the case is termed severe. If the onset is very rapid, as often occurs with severe clinical cases, it is termed an acute case of severe mastitis. More severely affected cows tend to have more serous secretions in the affected quarter.

Although any number of quarters can be infected simultaneously in subclinical mastitis, typically only one quarter at a time will display clinical mastitis. However, it is not uncommon for clinical episodes caused by *Mycoplasma* to affect multiple quarters. Gangrenous mastitis can also occur, particularly when subclinical, chronic infections of *S aureus* become severe at times of immunosuppression (eg, at parturition). As with subclinical mastitis, culture of milk samples collected from affected quarters is the only reliable method to determine the etiology of clinical cases.

Subclinical Mastitis

Epidemiology: All dairy herds have cows with subclinical mastitis; however, the prevalence of infected cows varies from 5%–75%, and quarters from 2%–40%. Many different pathogens can establish a chronic infection in which clinical signs of mastitis will manifest only occasionally. The primary focus of most subclinical mastitis programs is to reduce the prevalence of the contagious pathogens *S agalactiae* and *S aureus*, as well as other gram-positive cocci, most notably *Streptococcus dysgalactiae* (which may also be contagious or an environmental pathogen), *Streptococcus uberis*, enterococci, and numerous other coagulase-negative staphylococci, including *Staphylococcus hyicus*, *Staphylococcus epidermidis*, *Staphylococcus xylosus*, and *Staphylococcus intermedius*. Herds have been identified that have considerable subclinical mastitis caused by gram-negative rods such as *Klebsiella* sp, *Serratia marcescens*, *Pseudomonas aeruginosa*, and other atypical pathogens such as mycotic and algal microbes.

For contagious pathogens, adult lactating cattle are most at risk of infection, either while lactating or during the dry period. The primary reservoir of infection is the mammary gland; transmission occurs at milking with either milkers' hands or milking equipment acting as fomites. Primiparous heifers have been reported to be infected with staphylococci and streptococci before calving, although the prevalence varies greatly among herds and

geographic regions. Teat-end dermatitis caused by the horn fly, *Haematobia irritans*, which can harbor *S aureus*, has been associated with increased risk of infection in heifers, especially in warmer climates.

For the contagious pathogens and coagulase-negative staphylococci, there is little or no seasonal variation in incidence of infection.

Treatment: Therapy is given on the premise that treatment costs will be outweighed by production gains after elimination of infection. In the case of contagious pathogens, elimination may also result in a decrease of the reservoir of infection for previously noninfected cows. No significant economic losses will occur as a result of delaying therapy until bacterial culture can be completed. However, many subclinical cases selected as potential therapy candidates have chronic infections; particularly in the case of *S aureus*, prediction of therapeutic outcome by in vitro testing is unreliable. Drug distribution after intramammary administration may not be adequate because of extensive fibrosis and microabscess formation in the gland; it is critical to assess the cow's immune status from a perspective of duration of infection, number of quarters infected, and other variables.

Prevalence of *S agalactiae* infection can be rapidly reduced by treating an entire herd—or more economically, all the infected cows in a herd—with antibacterials. All four quarters of infected cows should be treated to ensure elimination of the pathogen and to prevent possible cross-infection of a noninfected quarter. Cure rates can often be 75%–90%. Labeled use of commercial intramammary products that contain amoxicillin, penicillin, and erythromycin are as efficacious as procaine penicillin G infusions derived from multiple-dose vials. Consequently, use of drugs originating from multiple-dose vials (labeled for systemic therapy) should not be used for intramammary therapy, because commercial intramammary preparations have superior quality control standards for sterility and better reliability to predict withholding periods for milk and meat after treatment. It is critical to apply strict aseptic techniques (use of alcohol swabs for teat-end preparation) whenever any intramammary infusion product is administered.

Herds undergoing extensive therapy for *S agalactiae* must be monitored by SCCs and bacteriology to further identify and treat

cows not identified or cured during the initial therapy. Usually, 30-day monitoring intervals are successful. A small percentage of cows will not respond to therapy and are best segregated or culled. In addition, failure to use postmilking teat dipping and total dry cow treatment to prevent new infections during the treatment period will ultimately result in reinfection of the herd. Parenteral therapy is not likely to offer any benefit over intramammary therapy.

Most other streptococci also display in vitro susceptibility to numerous antibacterials, especially β -lactam drugs. Despite this apparent susceptibility, many streptococcal infections are not as easily cured as those caused by *S agalactiae*. Generally, subclinical infections caused by *S uberis* and *S dysgalactiae* should be preferentially treated at the end of lactation with intramammary infusions of commercial dry cow products. Cure rates at this time may exceed 75%.

S aureus intramammary infections often result in deep-seated abscesses. Therapy is difficult, because resistance to antibacterials (particularly β -lactams) is more common than with streptococcal infections, and *S aureus* may survive intracellularly after phagocytosis when antibacterial concentrations are reduced. Intramammary infusions may cure only 35%–40% of infections; however, this number will be substantially lower for chronic infections.

The success rate of therapy for chronic subclinical intramammary infections caused by *S aureus* may be increased by using both parenteral and intramammary therapy. However, systemic therapy involves extra-label drug use, and milk and meat withholding periods must be determined judiciously. Therapy should be administered for periods long enough (7–10 days) to allow effective killing of the pathogen. It is most economical and least likely to result in residues in milk if this therapy is applied to dry cows. Depending on susceptibility testing, lipophilic antibacterial drugs that distribute well into mammary tissue, such as oxytetracycline (11 mg/kg/day) are the best candidates for systemic administration, although several studies have found oxytetracycline (administered for 4 days or less) to be ineffective. Cure rates may not be much better than those attained from spontaneous cure, and cure must be defined critically. Affected quarters should be monitored bacteriologically for ≥ 30 days to encompass the refractory period when bacteria may not be isolated.

Occasionally, premature agalactia will occur in chronically infected quarters, particularly quarters infected with resistant pathogens. Culling may be a practical option for these cows. Alternatively, it is common to dry off the infected quarter and continue to milk the cow. This may have some benefit for genetically superior animals within a herd or for cows that are to be maintained until calving. Anecdotally, the overall milk production from such cows may remain the same. The goal is to eliminate the infection by causing fibrosis of the affected quarter, thus reducing the risk of further pathogenic change or systemic effects on the cow, as well as reducing risk of infection for other cows.

Dry Cows: The dry period of the lactation cycle is a critical time for the udder health of dairy cows. The mammary gland undergoes marked biochemical, cellular, and immunologic changes. Involution of the mammary parenchyma begins 1–2 days after the end of lactation and continues for 10–14 days. During this time, the gland is particularly vulnerable to new intramammary infections. However, the involuted mammary gland offers the most hostile immune environment for bacterial pathogens. Consequently, the dry period is an ideal time to attain synergy between antibacterial therapy and immune function, without incurring the extensive costs typical of lactating cow therapy. Intramammary administration of antibiotics at the end of lactation has been a standard of dairy mastitis management for 30 yr and continues to help reduce the prevalence of mastitis in most dairy herds.

Numerous commercial products are available and include penicillin, cloxacillin, cephalixin, ceftiofur, or novobiocin. One tube per quarter is sufficient and should be administered immediately after the last milking of lactation. Therapy should not be repeated by intramammary infusion; if there is a need to extend therapy, systemic administration should be used as an adjunct to the intramammary infusion. In addition to eliminating existing subclinical infections, one of the most critical roles of dry cow therapy is to prevent new infections. However, most commercial dry cow products have little or no activity against gram-negative pathogens, and their administration at the start of the dry period will not be effective against new infections that begin during the periparturient period. The antimicrobial therapy can be supplemented by subsequent infusion of internal teat sealants that serve as a barrier to help reduce new infections.

Heifers: Many infections in calving heifers are caused by staphylococcal species other than *S aureus*, which have a high rate of spontaneous cure. However, under some herd conditions, a substantial portion of heifers are infected at calving; some of these infections are caused by pathogens such as *S aureus*. Potential sources include milk (fed to calves) and body sites such as tonsils and skin. There is also a geographic risk factor: fly bite dermatitis of the teat end, which compromises this important physical barrier to infection, may play a role in the pathogenesis.

Intramammary infusions of β -lactam antibacterial drugs 7–14 days before expected calving dates have been reported to reduce the rate of intramammary infections at calving. However, long-term benefits on SCCs, milk production, and incidence of clinical mastitis during lactation were found to be highly herd variable and not consistent. Strict teat-end antisepsis should be followed before infusion to prevent contamination; thus, labor to handle animals for treatment can be extensive. This is not a recommended management program for many dairies. However, if herd records indicate that an undesirable proportion of first-lactation animals are infected at calving, particularly with staphylococci, this regimen may be considered.

Prevention: New infections caused by *Sagalactiae* and *S aureus* can be prevented by focusing management efforts on milking technique and hygiene. Clean and dry bedding, clean and dry udders at the time of milking, and lack of teat-end lesions all have a positive effect on control. The single most important management practice to prevent transmission of new infections is the use of an effective germicide as a postmilking teat dip. These products should be applied as a dip (rather than a spray) immediately after milking. Other practices that augment teat dipping include use of individual towels for drying teats, gloves for milkers' hands, use of a premilking germicide (spray or dip), attachment of units at the proper time after teat stimulation (60–120 sec), cleaning milking units after an infected cow has been milked, or segregation of infected cows into a separate milk group. This last option may be unrealistic for cattle in free housing that are normally segregated for nutritional or reproductive reasons. Routine milking equipment evaluations should be conducted to ensure that the teat-end vacuum is operating

at a proper level and remains stable during milking. Proper pulsator function should be maintained, and liners and rubber air hoses should be replaced as needed.

Proper milking hygiene also reduces the new infection rate of noncontagious pathogens. More importantly for environmental pathogens, cows should be provided dry, clean housing. Emphasis should be placed on bedding and any other practices that reduce the exposure of the teat end to bacteria. Inorganic bedding supports less bacterial growth than cellulose-based material; thus, sand is preferred over sawdust, straw, recycled paper, or manure. In particular, higher incidence of infections caused by *Klebsiella* has been associated with sawdust bedding. Similarly, a higher incidence of infections caused by environmental streptococci has been associated with straw bedding. However, the concentrations of bacteria can vary greatly depending on moisture and presence of organic matter (such as in sand after recycling). Thus, identification of reservoirs of infection should not be based solely on the choice of bedding material. Regular cleaning or changing of bedding, reducing heat stress, removing udder hair, preventing teat trauma, reducing udder edema in periparturient cows by nutritional management of potassium and sodium intake, and preventing frostbite and fly exposure all have a positive impact on environmental mastitis control.

Clinical Mastitis

When the balance between host defenses and invading pathogens causes a marked inflammatory response, clinical signs become apparent. Infections from any pathogen can be clinical or subclinical, depending on the duration of infection, host immune status, and pathogen virulence. Control of clinical mastitis usually focuses on prevention and elimination of pathogens that arise from an environmental reservoir. Thus, the epidemiology and prevention of clinical mastitis is similar to previously discussed concepts regarding control of subclinical mastitis.

Epidemiology: Except for outbreaks of *Mycoplasma*, clinical mastitis in most dairy herds is caused by environmental pathogens. In addition, many clinical mastitis cases are transient, especially those that are initial episodes for a cow and quarter. Thus, from an epidemiologic perspective, assessment of clinical mastitis is based on incidence and not prevalence.

The standard methods to monitor subclinical mastitis, ie, routine somatic cell counts (SCCs) and culture of cows with increased SCCs, are poor predictors of herd clinical mastitis episodes. Cows with high SCCs caused by chronic infections may occasionally display clinical mastitis, although it is usually mild. However, cows with low SCCs are also prone to develop clinical mastitis. Herds with low SCCs may actually have a higher incidence of clinical cases caused by environmental organisms (as high as 30–50 cases/100 cows/yr) than herds with higher SCCs. Similarly, routine culture of milk samples from a cow with a low SCC is a poor indicator of the probability of developing clinical mastitis, especially if the culture yielded no organisms.

Thus, the incidence of clinical cases, and data from each case that may determine risk factors (eg, season, age, stage of lactation, and previous episodes), should be recorded as part of a mastitis control program. Milk samples should be collected from affected quarters and, when feasible, antibacterial susceptibility testing performed. For well-managed herds in which mastitis caused by contagious pathogens has been controlled, a goal for the incidence of clinical mastitis should be 1–2 cases/100 cows milking/mo. Severe mastitis cases should be in the range of 1–2 cases/100 cows milking/yr.

Typically, 3%–40% of milk samples collected from clinical mastitis cases yield no organisms on culture. However, of the samples that do yield organisms, 90%–95% of the isolated bacteria include a wide variety of streptococci, staphylococci, or coliforms. If this is not the case, especially if a single pathogen such as a noncoliform gram-negative rod or a mycotic or algal (*Prototheca* sp) predominates, a point source of infection should be considered.

Severe Clinical Mastitis: Coliforms (lactose-fermenting gram-negative rods of the family Enterobacteriaceae) are the most common cause of this form of mastitis. After infection, coliform numbers in milk increase rapidly, often attaining peak bacterial concentrations within a few hours. A subsequent decline (rapid in most cases but may take several days in truly severe mastitis) in bacterial concentration follows neutrophil migration into the gland. Most coliform infections are cleared from the gland with few or mild clinical signs. However, if bacterial concentrations are increased enough to elicit an acute inflammatory response, systemic involvement is a frequent consequence.

Mastitis caused by coliforms results in a higher incidence of cow death or agalactia-related culling (30%–40%) than mastitis caused by other pathogens (2%). Prognosis for cases of *Klebsiella* infection should be particularly guarded, because these cows are twice as likely to be culled or die than those infected by other coliforms. Thus, primary therapy for severe clinical mastitis should be directed against coliform organisms, although secondary consideration must be given for other causative agents. Supportive care, including fluids, is indicated, and in the case of coliform mastitis, may be the most beneficial component of the therapeutic regimen. Antibacterial therapy is ideally based on identification of the causative pathogen; however, this is not attainable for some hours after initial case recognition. In addition, most antibacterial therapeutic regimens currently used for severe clinical mastitis in the USA are not approved by the FDA.

Many inflammatory and systemic changes seen in severe coliform mastitis result from the effects of release of lipopolysaccharide (LPS) endotoxin from the bacteria and subsequent activation of cytokine and arachidonic acid-derived mediators of inflammation and the acute phase response. By the time therapy is initiated, maximal release of LPS has likely occurred. Thus, the primary therapeutic concern is the treatment of endotoxin-induced shock with fluids, electrolytes, and anti-inflammatory drugs. The IV route is preferred as the initial method of fluid administration. If isotonic saline is administered, 30–40 L are necessary throughout a 4-hr period, which can be difficult under farm conditions. A practical alternative is 2 L of 7% NaCl (hypersaline) administered IV. This induces rapid fluid uptake from the body compartment into the circulation. Cows should then be offered free-choice water to drink, and if at least 10 gal. is not consumed, 5–7 gal. should be pumped into the rumen. Many cows with endotoxic shock are marginally hypocalcemic; thus, 500 mL of calcium borogluconate should be administered SC (to avoid potential complications of IV administration). Alternatively, rapid absorption calcium gels, designed for periparturient hypocalcemia, can be given. If the cow remains in shock, continued fluid therapy should be administered PO or IV as isotonic, not hypertonic, fluids.

If administered early in the course of disease, glucocorticoids may be helpful in cases of mastitis caused by endotoxin-producing coliforms. Administration of

dexamethasone (30 mg, IM) to dairy cows immediately after introduction of *E. coli* into the mammary gland has been reported to reduce mammary gland swelling and inhibition of rumen motility. Isoflupredone (10–20 mg, IM) has also been shown to reduce local mammary swelling. Cattle are sensitive to glucocorticoid-induced immune suppression; however, it is unlikely that one-time administration of a glucocorticoid will adversely affect cows with endotoxin-induced severe clinical mastitis. Temporary suppression of inflammation as manifested by reduced neutrophil migration may well be beneficial. Care should be exercised in administering these drugs to pregnant animals; however, severe clinical mastitis in and of itself may cause pregnancy loss in cattle.

There is little published research on the use of glucocorticoids for mastitis caused by gram-positive bacteria. It is reasonable to expect that gram-positive infections would be less likely to benefit from the anti-inflammatory activities of glucocorticoids and may even be adversely affected. Intramammary glucocorticoid administration to reduce local inflammation, without affecting the migration of neutrophils into the gland, is an attractive therapeutic option. Although products that combine antibacterial and glucocorticoid drugs for intramammary administration exist in Europe, it is not clear whether clinical benefit is gained when compared with antibacterial therapy alone. As a general guideline, glucocorticoid treatment should be reserved for severe cases of gram-negative mastitis, with a single dose administered early in the disease course.

NSAIDs are widely used in treatment of acute mastitis. Flunixin meglumine, flurbiprofen, carprofen, ibuprofen, and ketoprofen have been studied as treatments for experimental coliform mastitis or endotoxin-induced mastitis. Systemic use of these drugs is preferred over orally administered aspirin, which is not likely to attain effective concentrations in tissue or lead to beneficial results. Dipyrone use in food animals is specifically prohibited by the FDA. Phenylbutazone is prohibited in dairy cattle >20 mo old; the tolerance level for phenylbutazone is zero, and detection of any concentration is an illegal residue. Thus, these two drugs should not be used for anti-inflammatory therapy for mastitis in cattle.

Treatment with ketoprofen improved recovery of cows with acute clinical mastitis in a blinded, placebo-controlled study. Ketoprofen is available as a

veterinary product for use in horses, has a high therapeutic index, has favorable pharmacokinetics for use in lactating dairy cattle, and is approved for use in cattle in France; however, it is not labeled for food animal use in the USA. The Food Animal Residue Avoidance Databank (FARAD) recommends withdrawal intervals of 7 days for slaughter and 24 hr for milk, with IV or IM administration, for dosages up to 3.3 mg/kg/day, for up to 3 days.

Flunixin meglumine is labeled for beef and dairy cattle. It is the only NSAID labeled for use in cattle in the USA and is therefore the most logical choice for treating clinical mastitis. In field studies, increased survival and improved milk production have not been demonstrated after treatment of clinical acute mastitis with flunixin meglumine at a dosage of 1.1 mg/kg. However, in studies of experimental mastitis, flunixin meglumine reduced the severity of clinical signs such as fever, depression, heart and respiratory rates, and udder pain. The FDA-approved withdrawal intervals are 4 days for slaughter and 36 hr for milk when used as labeled by IV administration. Because of extensive and unpredictable withdrawal periods, this drug should *not* be administered by IM injection. As with the glucocorticoids, NSAIDs may provide symptomatic relief and promote well-being. Administration early in the course of infection is likely to increase clinical benefit.

Antibacterial therapy may be of secondary importance relative to immediate supportive treatment of endotoxic shock, but it remains an integral part of a therapeutic regimen. Occasionally, coliform infections do result in chronic mastitis. Research suggests that bacteremia may occur in >40% of severe coliform cases. In addition, numerous other pathogens, including gram-positive cocci, cause severe clinical mastitis, which can be difficult to distinguish from cases caused by coliforms at initial presentation.

Selection of an appropriate antibacterial for severe coliform mastitis depends primarily on the susceptibility of the organism to the selected drug and the ability to maintain effective concentrations at the primary pharmacologic target (which, in the case of coliform mastitis, is the plasma compartment of the cow).

In one study, IM gentamicin was not more effective in preventing agalactia or death resulting from severe coliform mastitis, or in improving other clinical outcomes, than IM erythromycin or no systemic antibacterials. Cows experimentally challenged with *E*

coli and treated with 500 mg of intramammary gentamicin bid did not have lower peak bacterial concentrations in milk, duration of infection, convalescent SCCs or serum albumin concentrations in milk, or rectal temperatures than untreated challenged cows. In addition, gentamicin readily diffused through the milk-blood barrier, resulting in drug residues in the kidney that could extend beyond 18 mo. Because of zero tolerance for aminoglycoside residues at slaughter, the use of this class of drugs in dairy cattle is *not* recommended.

Oxytetracycline (11 mg/kg/day, IV) improved outcome of cows with clinical coliform mastitis (not necessarily severe) as compared with cows that did not receive systemic antibacterials. Ceftiofur sodium (2.2 mg/kg/day, IM) decreased the mortality and cull rates of cows with severe coliform mastitis. This drug distributes poorly to the mammary gland, supporting the emphasis on treating the cow rather than the mammary gland because of the risk of septicemia.

Intramammary infusion of commercial products that have good activity against gram-positive organisms should be administered to any cow with severe clinical mastitis. This treatment is not likely to affect the outcome of a case caused by coliforms but may provide some benefit for cases caused by gram-positive cocci. The need for antibacterial therapy in cows with grossly abnormal milk, but with improved appetite, attitude, and milk production, should be evaluated critically. Unnecessary extension of therapy in these instances results in increased discarded milk expense for the dairy producer and risk of antibacterials in marketed milk.

Mild Clinical Mastitis: No microorganisms are isolated from 30%–40% of bacteriologic cultures of milk samples collected from cows with clinical mastitis. Many mild mastitis cases that fail to yield bacteria on culture are coliform intramammary infections that resolve before treatment is necessary. In addition, numerous mild clinical mastitis cases are temporary setbacks in the balance between pathogen and host defenses that occurs in more chronic intramammary infections. A “no antibiotic” approach to mild clinical mastitis cases avoids costs of discarded milk and residue risks inherent in antibacterial therapy.

A comparison of cure rate in treated versus untreated cows in a study of three California dairies found bacteriologic cure

assessed at 4 and 20 days after treatment with amoxicillin, cephalixin, or oxytocin (no antibacterial) did not differ for mild clinical mastitis cases caused by streptococci and coliforms. However, the rates of both relapses and recurring cases were higher in untreated cows, especially among streptococcal cases. In a Colorado dairy study, a no-antibiotic approach also increased the rate of relapses, with an increase in the incidence of clinical mastitis, prevalence of intramammary infections, and herd SCCs associated with streptococcal infections. If bacterial culture of affected quarters yields no organisms or coliforms, therapy is not likely to be beneficial, whereas if gram-positive cocci are isolated, therapy is recommended.

Common sense and individual herd history should determine the course of therapy for mild clinical mastitis cases in dairy herds. Use of approved commercial intramammary infusions is likely to be the best option. Assessment of success should be based on bacteriologic cure but will be more practically based on return to normal milk. However, the frequency of relapsed cases should be monitored as the best means to determine cures, because many cases will be deemed to have been successfully treated initially but relapse later in lactation. If mastitis recurs regularly in affected quarters in the absence of systemic signs, repeated treatment of what now has become chronic intramammary infection is not warranted. Additionally, augmentation with parenteral therapy for these cases has not been demonstrated to be effective and will not likely overcome the expense of discarded milk, other related treatment costs, and the increased risk of residues in milk and meat. Previous history of clinical cases ("repeat offenders"), long duration of infection (as exhibited by high individual SCCs or extended periods of increased SCCs), and infections caused by nonresponsive pathogens are the greatest risk factors for poor therapeutic outcome. Practitioners should develop a protocol with dairy clients to reduce unnecessary treatment of poor risk cases as listed above and not rely on continued unsuccessful therapy or seeking a "better drug."

If standard regimens achieve less than desired results, it would be better to extend initial therapy for a prolonged period rather than to change to other antibacterial drugs or increase the amount of each dose. Studies have demonstrated improved cure rates for gram-positive cocci, especially coagulase-negative staphylococci and streptococci, when infected quarters were

treated with intramammary infusions for up to 8 days as compared with 2 or 5 days. Care should be especially exercised in teat asepsis for extended therapy because of the increased risk of nosocomial infections.

Unusual Pathogens: *Pseudomonas aeruginosa* may cause outbreaks of clinical mastitis. Generally, a persistent infection occurs, which may be characterized by intermittent acute or subacute exacerbations. The organism is found in soil-water environments common to dairy farms. Herd infections have been reported after extensive exposure to contaminated wash water, teat cup liners, or intramammary treatments administered by milkers. Failure to use aseptic techniques for udder therapy or use of contaminated milking equipment may lead to establishment of *P. aeruginosa* infections within the mammary glands. Severe peracute mastitis with toxemia and high mortality may follow immediately in some cows, whereas subclinical infections may occur in others. The organism has persisted in a gland for as long as five lactations, but spontaneous recovery may occur. Other than supportive care for severe episodes, therapy is of little value. Culling is recommended for cows.

Trueperella (formerly *Arcanobacterium*) *pyogenes* is common in suppurative processes of cattle and pigs and produces a characteristic mastitis in heifers and dry cows. It is occasionally seen in mastitis of lactating udders after teat injury, and it may be a secondary invader. The inflammation is typified by the formation of profuse, foul-smelling, purulent exudate. Mastitis due to *T. pyogenes* is common among dry cows and heifers that are pastured during the summer months on fields and that have access to ponds or wet areas. The vector for animal-to-animal spread is the fly *Hydrotaea irritans*. Control of infections is by limiting the ability to stand udder-deep in water and by controlling flies. Preventive treatment of heifers and dry cows in susceptible areas with long-acting penicillin preparations has effectively reduced infections. Therapy is rarely successful, and the infected quarter is usually lost to production. Infected cows may be systemically ill, and cows with abscesses usually should be slaughtered. (See also ACTINOMYCOSIS, p 590.)

Mycoplasma spp can cause a severe form of mastitis that may spread rapidly through a herd with serious consequences. *M. bovis* is the most common cause. Other significant species include *M. californicum*, *M. canadense*, and *M. bovis genitalium*.

Onset is rapid, and the source of infection is believed to be endogenous after outbreaks of respiratory disease in heifers or cows. The disease is often seen in herds undergoing expansion in which animals from outside sources have been added. Typically, introduced animals will be asymptomatic carriers and then shed the organism via respiratory or intramammary transmission. Some or all quarters become involved. Loss of production is often dramatic, and the secretion is soon replaced by a serous or purulent exudate. Initially, a characteristic, fine granular or flaky sediment may be seen in the material removed from infected glands. Despite the severe local effects on udder tissue, cows usually do not manifest signs of systemic involvement. The infection may persist through the dry period. Identification of infected cows can be difficult because of the frequent propensity of these cows to become asymptomatic carriers and intermittently shed the organism in milk.

Because there is no satisfactory treatment, affected cows should be segregated during active outbreaks. Routine screening of the bulk tank and milk strings may help identify the presence of infected cows. However, culture of the mammary secretion of cows with clinical mastitis, or recently calved cows, is the most reliable surveillance method. If cows continue to display clinical mastitis or systemic signs, they should be culled. Sanitary measures should be strictly enforced, especially at milking and in hospital/treatment areas. Milk from *Mycoplasma*-infected cows should not be fed to calves, because this may result in respiratory and inner ear infections. Milk replacer or pasteurized milk, rather than discarded milk, should be fed to calves in herds with *Mycoplasma*.

Nocardia asteroides causes a destructive mastitis characterized by acute onset, high temperature, anorexia, rapid wasting, and marked swelling of the udder. Response in the udder is typical of a granulomatous inflammation and leads to extensive fibrosis and formation of palpable nodules. Herd histories suggest that infection of the udder may be associated with failure to ensure asepsis in intramammary treatment of the common forms of mastitis. Slaughter is recommended for infected cows.

Serratia mastitis may arise from contamination of milk hoses, teat dips, water supply, or other equipment used in the milking process. The organism is resistant to disinfectants. Cows with this form of mastitis that continue to display clinical signs should be culled.

Mastitis due to various mycotic organisms (yeasts) has appeared in dairy herds, especially after the use of penicillin in association with prolonged repetitive use of antibiotic infusions in individual cows. Yeasts grow well in the presence of penicillin and some other antibiotics; they may be introduced during udder infusions of antibiotics, multiply, and cause mastitis. Yet, heifers that have never received intramammary infusions may develop yeast mastitis. Signs may be severe, with a fever followed either by spontaneous recovery in ~2 wk or, more rarely, by a chronic destructive mastitis. Other yeast infections cause minimal inflammation and are self-limiting. If mastitis due to yeast is suspected, antibiotic therapy should be stopped immediately. Yeast or other mastitis infections can be reduced if the tip of the plastic infusion tube is only partially (rather than completely) inserted through the teat canal during intramammary therapy.

A chronic, indurative mastitis similar to that caused by the tubercle bacillus has been reported to be caused by acid-fast *Mycobacterium* spp derived from the soil, such as *M. fortuitum*, *M. smegmatis*, *M. vaccae*, and *M. phlei* when such organisms are introduced into the gland along with antibiotics (especially penicillin) in oil or ointment vehicles. The oil apparently enhances the invasiveness of these organisms, and such therapy is contraindicated. These organisms otherwise tend to be saprophytic and to disappear from infected quarters, at least by the next lactation. In the meantime, mastitis is usually moderate. Distinct outbreaks do occur and several have been reported, especially with *M. fortuitum* and *M. smegmatis*.

Prototheca sp are nonpigmented unicellular algae commonly found in wet environments such as streams, stagnant ponds, and marine waters, particularly in humid habitats with organic matter in the soil. In dairy farm environments, they are especially abundant in muddy or wet outdoor runs or lots, resting areas, paths where animals are driven, and pastures contaminated with slurry. Protothecal mastitis in dairy cattle is often chronic and asymptomatic with increased SCCs, although sporadic severe infections occur. Although some infections may spontaneously resolve, longterm carriage with intermittent shedding is common. After initially causing clinical mastitis, infections may be undetectable by culture of milk for several months, only to recur during the subsequent lactation, particularly soon after calving. Therapeutic interventions are

unrewarding. Thus, dairy producers have limited ability to predict the progression or affect the outcome of protothecal mastitis and are constrained to management options similar to those used to manage chronic mastitis caused by other pathogens. Therefore, the primary management focus is prevention rather than mitigation of infections. To reduce pathogen exposure to other noninfected cows in the herd, chronic mastitic cows are often culled. The primary causative agent of protothecal mastitis in cattle has been identified as *P. zopffii*. Other reports have challenged the absolute exclusivity of *P. zopffii* as the etiologic agent of protothecal mastitis, but on a practical basis cows identified as having mastitis caused by *Prototheca* sp are managed in similar fashion, regardless of species or genotype.

Prevention: Bacterins made using core-antigen technology based on J5 mutant *E. coli* can help reduce the severity of clinical mastitis caused by coliforms. Vaccination programs using these bacterins should minimally include multiple administration during the dry period to reduce the incidence of clinical coliform mastitis frequently associated with early lactation. Protocols for extended numbers of immunizations of these bacterins may be warranted in herds with high rates of severe mastitis beyond 60 days in milk, because protection often wanes 50–60 days after the last immunization.

MASTITIS IN GOATS

The organisms infecting the udder of goats are similar to those in cows. Coagulase-negative staphylococci are generally the most prevalent and can cause persistent infections that result in increased cell counts and low-grade mastitis with some recurring clinical episodes. The level of infection and incidence of mastitis due to *Staphylococcus aureus* tends to be low (<5%) but can result in persistent infections that do not generally respond to therapy. Streptococcal intramammary infections can occur in both subclinical and clinical cases but are usually much less frequent than in cattle. *Streptococcus agalactiae* is not a common pathogen of mastitis in does.

Mycoplasma infections, primarily *M. mycoides* (large colony type) and *M. putrefaciens*, sometimes cause serious outbreaks of mastitis in goats (see p 1352). The latter also causes septicemia, poly-arthritis, pneumonia, and encephalitis, together with serious disease and mortality

in suckling kids. *M. capricolum* has also been reported to cause severe mastitis in goats and infection in kids. Does usually recover in ~4 wk.

As with cows, gram-negative organisms cause intermittent infections that may be severe but are usually self-limiting. *Trueperella* (formerly *Arcanobacterium*) *pyogenes* sometimes produces multiple, nodular abscesses.

Does can also exhibit signs of mastitis from caprine arthritis and encephalitis (see p 747) and ovine progressive pneumonia (see p 1475) secondary to systemic infection. Agalactia is common, as is a hardening of the udder from fibrosis.

Programs for diagnosis, control, and treatment of bacterial mastitis in goats are similar to those in cows. However, monitoring subclinical mastitis with somatic cell counts (SCCs) in does is difficult because of poor discrimination between infected and noninfected animals, especially in the later stages of lactation. This is partially because a higher proportion of cells are epithelial in origin in goat milk than in cow milk. As lactation progresses, shedding of epithelial cells into milk increases; thus, SCCs >1,000,000 cells/mL are common in uninfected does in late lactation. Proper milking procedures and good environmental sanitation are needed to reduce the prevalence and spread of infection. Chronically infected goats should be culled, as should goats with *M. mycoides* infections and those that do not recover from *M. putrefaciens* or *M. capricolum* infections.

MASTITIS IN EWES

Mastitis can be an important disease in sheep, with an incidence >2%. In addition to deaths from severe infections, the disease can be a cause of lamb mortality from starvation or of depressed weaning weights of lambs. Peracute, gangrenous (usually due to *Staphylococcus aureus*), acute, subacute, and probably subclinical types occur. The organisms most commonly involved are *S. aureus*, coagulase-negative staphylococci, streptococci, *Escherichia coli*, *Mannheimia haemolytica*, and *Trueperella* (formerly *Arcanobacterium*) *pyogenes*.

The principles of diagnosis and treatment used in bovine mastitis can be applied to ewes. Little is known about the control of ovine mastitis, but careful inspection of the mammary glands of ewes before mating to detect and eliminate those with chronic mastitis should be beneficial.

MASTITIS IN MARES

Acute mastitis occurs occasionally in lactating mares, most commonly in the drying-off period, in one or both glands. *Streptococcus zooepidemicus* is the most frequent pathogen, but *S equi*, *S equisimilis*, *S agalactiae*, and *S viridans* are also found. A variety of gram-negative bacteria has also been reported. Marked, painful swelling of the affected gland and adjacent tissues develops, and the secretion is often seroflocculent. Fever and depression may be present. The mare may walk stiffly or stand with hindlegs apart due to the discomfort.

Treatment is similar to that in cows, but when intramammary infusions are used, they should be inserted separately into both orifices of the teat. Systemic therapy has been suggested to include trimethoprim-sulfonamide (based on 5 mg/kg of trimethoprim, PO, bid) or a combination of penicillin (20,000 IU/kg, IM, bid) and gentamicin sulfate (2 mg/kg, IV, tid). Therapy should be continued on the basis of culture and antibacterial sensitivity testing. Without prompt treatment, abscessation or induration of the gland can occur. Little is known about the frequency and persistence of subclinical intramammary infections in mares.

MASTITIS IN SOWS

Mastitis can be important in swine-raising units. Peracute mastitis can affect sows and gilts and is most commonly associated with coliform (*Escherichia coli*, *Enterobacter aerogenes*, and *Klebsiella*) infections. It is most common at or just after parturition, and affected sows have a moderate to

severe toxemia. The sow's temperature may increase to 107°F (42°C) or may be subnormal. The affected glands are swollen, purple, and have a watery secretion. Sow mortality is high, and the piglets will die unless fostered or fed artificially. Milk production of recovered sows may be impaired in the next lactation. The treatment of peracute coliform mastitis in sows is similar to that in cows. Ampicillin, dihydrostreptomycin, or oxytetracycline administered systemically have been used. Treatment of lactating sows requires consideration of withholding periods, because affected sows are often culled after weaning.

Subacute mastitis may occur in older sows and lead to induration of one or more glands, impairing the sow's ability to nurse a large litter. This form of mastitis is more likely to be associated with infection by streptococci or staphylococci. Granulomatous lesions in the mammary glands of sows have been associated with *Actinobacillus lignieresii*, *Actinomyces bovis*, and *Staphylococcus aureus* infections. *Fusobacterium necrophorum* and *Trueperella* (formerly *Arcanobacterium pyogenes*) also have been incriminated in sow mastitis. A thorough examination and culture of the mammary glands of the sow are important to diagnose any of the above peracute and subacute types of mastitis. (See also POSTPARTUM DYSGALACTIA SYNDROME, p 1373.)

The control of mastitis in sows has not been extensively investigated, but isolating sows in adequately disinfected pens before, during, and for an adequate period after farrowing should help prevent the severe losses associated with coliform mastitis.

METRITIS IN LARGE ANIMALS

ACUTE PUERPERAL METRITIS

In all species, acute puerperal metritis occurs within the first 10–14 days postpartum. It results from contamination of the reproductive tract at parturition and often, but not invariably, follows complicated parturition. Important causative organisms in cattle include *Escherichia coli* and *Trueperella* (*Arcanobacterium*) *pyogenes*, but culture-independent studies have

demonstrated the dominant role of gram-negative anaerobic bacteria such as *Prevotella melaninogenica* and *Fusobacterium necrophorum*. The condition is usually acute in onset. Affected cows, mares, ewes, does, or sows are depressed, febrile, and inappetent. A fetid, watery uterine discharge is characteristic of the condition in cows but may not be conspicuous in other species. Milk production is diminished, and nursing young may show signs of food deprivation.

Acute puerperal metritis responds well to systemic antimicrobial therapy combined, if necessary, with NSAIDs and other supportive measures such as fluid therapy. Cephalosporin antibiotics or penicillin are considered most appropriate for systemic treatment of cows with metritis because they are active against most common pathogens, reach therapeutic levels in endometrial tissues, and may help prevent some of the potential sequelae of metritis and endometritis, such as endocarditis or renal disease. Oxytetracycline requires administration at high levels (11 mg/kg, bid) to maintain uterine tissue concentrations of 5 mcg/g, which is below the minimal inhibitory concentration (MIC) for many strains of pathogenic *T. pyogenes*. Drainage of the uterine content may be advantageous but should be attempted only after initiation of antimicrobial therapy; it should be done very carefully because the inflamed uterus may be friable, and manipulation of the uterus may result in bacteremia.

METRITIS AND ENDOMETRITIS

Cows: Several specific diseases are associated with metritis or endometritis. These include brucellosis (see p 1348), leptospirosis (see p 646), campylobacteriosis (see p 1347), and trichomoniasis (see p 1384). More often, endometritis is the result of nonspecific infections.

The normal uterus is a sterile environment, in contrast to the vagina, which hosts numerous microorganisms. Opportunistic pathogens from the normal vaginal flora or from the environment may invade the uterus from time to time. A healthy uterus is able to rid itself of these transient infections very efficiently; however, in the immediate postpartum period, the uterus of cows is usually contaminated with a variety of organisms. Within days or weeks postpartum, the sterile uterine environment is reestablished in most animals. In those in which infection persists, chronic or subacute endometritis develops and has a detrimental effect on fertility. The prevalence of subclinical endometrial inflammation in dairy cows seems to exceed the prevalence of uterine infection. The pathogenesis of this form of endometritis is not yet understood, but it is becoming increasingly clear that postpartum uterine diseases, particularly in high-producing dairy cows, are mediated by impaired immune response, probably related to negative energy balance.

In cows, the causative organisms are most often *Trueperella pyogenes*, alone or in association with *Fusobacterium*

necrophorum or other gram-negative anaerobic organisms. Signs of infection vary from obvious and persistent purulent exudate from the uterus to inapparent infection. Changes in uterine consistency may occur, but transrectal palpation alone is an insensitive means of diagnosis. The presence of purulent exudate in the vagina does not necessarily confirm endometritis; the source of the exudate may be the cervix or, occasionally, the vagina itself. Manual vaginal examination or use of a device to recover vaginal content may also allow evaluation of vaginal exudates for diagnosis of clinical endometritis. Diagnosis of subclinical (cytologic) endometritis requires use of endometrial cytology, ultrasonography, or endometrial biopsy, because other signs are often absent. Cows with endometritis do not exhibit any systemic signs of illness, and appetite and milk production are usually unimpaired.

For decades, endometritis in cows has been treated with intrauterine infusion. Although infusion of antimicrobials may rid the uterus of bacteria, there is little evidence that it eliminates the endometrial inflammation or restores fertility. Many preparations routinely administered into the bovine uterus are detrimental to uterine tissue. Increased concern about milk and carcass residues, along with poor or uncertain results, should discourage intrauterine therapy as a routine approach to management of bovine endometritis. Intrauterine infusion of cephalirin in a form specially formulated for intrauterine use, and available in many countries (but not the USA), has enhanced fertility in dairy cows with endometritis. Systemic use of antimicrobials for treatment of clinical or subclinical endometritis has not been evaluated.

Cows are more resistant to uterine infection during estrus, and as cows undergo more estrous cycles after parturition, the prevalence of endometritis diminishes. This has led to increased use of prostaglandin $F_{2\alpha}$ or its analogues, at usual luteolytic doses, for the management of endometritis, although there is little evidence that such use reduces the incidence or effect of endometritis.

Mares: Although profound endometritis accompanies contagious equine metritis (see p 1371) in mares, most breeding problems are related to endometritis caused by nonspecific infections. In mares, the most common etiologic agent of endometritis is *Streptococcus zooepidemicus*, but several other organisms may be involved, including *Escherichia coli*, *Pseudomonas*

aeruginosa, and *Klebsiella pneumoniae*. Yeasts and fungi are incriminated in some cases, particularly in mares with reduced resistance, or as a sequela of exuberant antimicrobial therapy.

Visible exudate is rarely a feature of endometritis in mares. (Contagious equine metritis is a notable exception.) Endometrial inflammation is best confirmed by examination of endometrial cytology or biopsy samples. Additional support of the diagnosis is provided by ultrasonographic demonstration of intraluminal free fluid, especially during diestrus, or by isolation of potentially pathogenic bacteria from appropriately guarded swabs of the endometrium. Because most causative organisms are common commensals, isolation of bacteria alone is not sufficient evidence for diagnosis. Nevertheless, evidence suggests that fertility of mares is impaired if either endometrial cytology or culture is positive.

Intrauterine therapy is still commonly used in mares. Many antimicrobial drugs have been used, and effective doses determined mainly empirically. Some examples include penicillin (5 million U; effective mainly against *S. zooepidemicus*), ticarcillin (6 g; broad spectrum), ampicillin (3 g of soluble preparation), gentamicin (2 g, buffered with bicarbonate; effective especially against gram-negative agents), and kanamycin (2 g; effective against gram-negative bacteria). For fungal or yeast infections, 100 mg of amphotericin B or 500 mg of clotrimazole have been effective. Treatment should be continued for several consecutive days, preferably during estrus. Most of the above treatments constitute extra label drug use in the USA.

Some mares appear particularly susceptible to postbreeding endometritis. These mares accumulate fluid in the uterine lumen after mating or insemination. This is related to persistent endometrial inflammation. In contrast, normal mares have a vigorous, but transient, inflammatory response to mating, and the uterus rapidly regains its sterile, noninflamed status. Postbreeding endometritis may be treated by uterine lavage or by use of oxytocic drugs to rid the uterus of fluid.

Sows: A form of endometritis characterized by profuse vaginal discharge at the onset of estrus has been described in Europe and other regions. The causative agent is usually *Staphylococcus hyicus* or *E. coli*, and the disease seems to be transmitted at mating or artificial insemination; signs are seen 15–25 days later during the subsequent proestrus or estrus.

Infection may be of long duration, with signs recurring at each estrus. Some sows recover spontaneously, but there does not seem to be any effective treatment for those that do not. At necropsy, copious quantities of purulent exudate may be found in the uterus, making this condition more akin to pyometra (see below).

Other Species: Endometritis has been seen in sheep, goats, and camelids. In commercial sheep and goat flocks, diagnosis is seldom made antemortem, and treatment is generally impractical. In animals with a persistent uterine discharge, remnants of a macerated fetus should be considered as a nidus of chronic infection. Endometritis in camelids is usually treated empirically based on treatments for cattle and horses.

PYOMETRA

Pyometra is characterized by accumulation of purulent or mucopurulent exudate in the uterus. In cows, it is invariably accompanied by persistence of an active corpus luteum and interruption of the estrous cycle. In affected mares, the cervix is often fibrotic, inelastic, affected with transluminal adhesions, or otherwise impaired. Mares may continue to cycle normally, or the cycle may be interrupted. Discharge from the genital tract may be absent or intermittent and corresponding to periods of estrus. In general, affected animals do not exhibit any systemic signs of illness, but affected mares may be in poor condition. In both cows and mares, pyometra must be distinguished carefully from pregnancy before treatment is undertaken.

The treatment of choice in cows is administration of prostaglandin $F_{2\alpha}$ or its analogues at normal luteolytic doses. Expulsion of exudate and bacteriologic clearance of the uterus follows in ~80% of treated cases. Although first-service conception rate after treatment may be low, most cows may be expected to conceive within three or four inseminations. The treatment may need to be repeated in ~20% of cows. No intrauterine treatment is recommended in conjunction with the prostaglandin.

In the face of cervical changes, drainage of the affected equine uterus may be virtually impossible. Lavage of the uterus using large volumes of fluid is recommended; however, the condition frequently recurs, and permanent cure in these cases requires hysterectomy or wedge resection of the cervix to allow continual uterine drainage, a salvage procedure that allows continued use of the mare but renders her infertile.

Pyometra is seen in small ruminants, swine, and other species; diagnosis is rendered more difficult by animal size and management practices. If pyometra is diagnosed, evacuation of the uterus is recommended.

CONTAGIOUS EQUINE METRITIS

Contagious equine metritis (CEM) is an acute, highly contagious venereal disease of horses (and experimentally of donkeys) characterized by a profuse, mucopurulent vaginal discharge and early return to estrus in most affected mares. Infected stallions and chronically infected mares show no clinical signs. The disease is seen primarily in Europe, but technical challenges in propagation of the causative organism prevent accurate determination of the precise distribution of the disease.

Etiology and Transmission: CEM is caused by the gram-negative, microaerophilic coccobacillus *Taylorella equigenitalis*, also known as the contagious equine metritis organism (CEMO). Important strain differences exist; some strains are resistant to streptomycin (a fact that helps isolate this fastidious, slow-growing organism from contaminants), whereas others are sensitive to streptomycin. It is best cultured on chocolate Egon agar at 37°C in an atmosphere of 5%–10% CO₂ in air. *T. equigenitalis* is asaccharolytic but is positive for catalase, cytochrome oxidase, and phosphatase and unreactive to other conventional biochemical tests.

CEM is transmitted primarily at mating, but infected fomites (instruments and equipment) also play a role. Undetected infected mares and stallions are the source of new outbreaks. Infected stallions show no signs and harbor the organism in the smegma of the prepuce and the surface of the penis, especially in the urethral fossa. The transmission rate is exceptionally high; virtually every mare mated by an infected stallion becomes infected.

Clinical Findings: In mares, a copious, mucopurulent vaginal discharge is seen 10–14 days after infected matings. Mares may return to estrus after a shortened estrous cycle. Although the discharge subsides after a few days, mares may remain infected for several months. Chronically infected mares show no signs. Most mares do not conceive at the time of infected mating. If they do, they may infect the foal at or shortly after birth. Foals so infected may become carriers of CEMO when they reach sexual maturity.

Lesions: Lesions consist of edema and hyperemia of the endometrium, the endocervix, and the vaginal mucosa. The microscopic lesions include invasion of the affected tissues by neutrophils during the acute stage, and by lymphocytes, macrophages, and plasma cells later in the course of the infection.

Diagnosis: Diagnosis depends on isolation of the causative organism. Although other bacterial infections of the genital tract of mares may produce a conspicuous vaginal discharge, this is uncommon, and no other venereal pathogen of the equine reproductive tract is as contagious. In mares, swabs for culture should be taken from the endometrium (preferably during estrus) and from the clitoral fossa and sinuses. Swabs from suspected stallions should be taken from the urethral fossa, the urethra, the preputial cavity, the shaft of the penis, and, if possible, the preejaculatory fluid or ejaculate. Stallions should be sampled at least three times before being declared free of CEMO. Test-mating suspect stallions to susceptible mares that are then screened bacteriologically constitutes a satisfactory way to determine CEM status. All swabs should be placed in a transport medium (preferably Amies with charcoal), kept on ice or at 4°C, and delivered to a qualified laboratory within 24 hr (or frozen if transport will take longer). A variety of serologic tests has been developed, but none is yet capable of reliably detecting the carrier status.

Treatment and Control: Stallions can be treated by thoroughly cleaning the extended penis with chlorhexidine surgical scrub and then applying nitrofurazone ointment. This should be repeated daily for 5 days, and the stallion retested at least 10 days after treatment. Most mares rid themselves of uterine infection after a few weeks. Those that become chronically infected harbor the CEMO in the clitoral fossa or sinuses. They can be treated by thoroughly cleaning the clitoral area with chlorhexidine surgical scrub and then applying nitrofurazone ointment (as for the stallion). In some mares, surgical excision of the clitoral sinuses may be required to rid them of infection.

Control of CEM depends on identification of infected carrier animals and on their treatment or elimination from breeding programs. Strict import regulations exist in many countries to avoid the introduction of CEM, and current prevalence of the disease appears to be low.

POSTHITIS AND VULVITIS IN SHEEP AND GOATS

Two common and distinct forms of posthitis and vulvitis are recognized in small ruminants. The first, referred to as enzootic posthitis and vulvitis, is associated with high-protein diets, infection with *Corynebacterium renale* or other urease-producing organisms, locally high concentrations of ammonia, and severe posthitis. The second is referred to as necrotic or ulcerative balanoposthitis and vulvitis. Its cause is unclear, but *Mycoplasma mycoides mycoides* is implicated, as are other *Mycoplasma* spp organisms of the *Histophilus/Haemophilus* group, and potentially viruses, such as caprine herpesvirus 1.

ENZOOTIC POSTHITIS AND VULVITIS

(Sheath rot, Pizzle rot, Enzootic balanoposthitis)

Etiology and Epidemiology: This moderately contagious disease is caused by *C. renale*, a gram positive, diphtheroid bacterium capable of hydrolyzing urea. When protein intake is high, urinary urea concentration increases. Hydrolysis of urea by *C. renale* results in local production of large quantities of ammonia, which is believed to irritate the penis, lamina interna of the prepuce, and skin surrounding the preputial orifice. The condition is more common in male castrates, probably because of the hypoplastic nature of the penis, exacerbated in some cases by failure of penile-preputial separation that leads to pooling of urine in the prepuce. If preputial hair is cut too short or becomes caked with mud or organic matter, drainage of urine away from the preputial orifice (normally facilitated by this hair) is impaired, and ulcerative lesions may develop.

The incidence of ulcerative posthitis is highest in Merino and Angora wethers, which is attributed to the long hair or wool surrounding the prepuce in these animals, allowing urine to soak the area, which in turn is conducive to bacterial growth and activity. It is also seen in show rams or rams that have been fit for sale; in this case, the condition is more associated with dietary protein levels. The condition can be transmitted experimentally by infective

material from a preputial or vulvar ulcer. Ulcerative posthitis or vulvitis has a seasonal occurrence that varies with local animal husbandry methods. Peak incidence corresponds to the time when animals graze lush green pasture (eg, spring and early summer in New Zealand or autumn and winter in southern Brazil) or are fed or have access to high-protein feedstuffs.

Clinical Findings: In mild cases, signs are limited to swelling of the prepuce. In severe cases, swelling and inflammation interfere with urination and result in straining, which needs to be differentiated from urolithiasis (see p 1502). Histologic characteristics are acanthosis, parakeratosis, and hyperkeratosis, followed by leukocyte invasion and ulceration. Ulcers and scabs may be found around the preputial orifice, on the lamina interna of the prepuce, and on the shaft of the penis. Urine and exudate may accumulate in the prepuce. The condition may cause severe discomfort. If the preputial orifice or urethra is occluded, affected animals may die. Ulcerative vulvitis begins with signs of vulvar inflammation, including swelling and redness, and progresses to development of a yellow exudate with ulceration and scab formation around the vulva, vestibule, and caudal vagina. The glans clitoridis may be swollen, red, and ulcerated.

Lesions of ulcerative posthitis or vulvitis should be distinguished from those of granular posthitis or vulvitis (associated with *Mycoplasma* spp or *Ureaplasma* spp, see p 1391), herpesviral balanoposthitis or vulvovaginitis, ulcerative dermatosis (see p 872 [sheep only]), or contagious ecthyma (orf, see p 866 [goats only]). Removal of the scabs of ulcerative posthitis or vulvitis characteristically results in little or no hemorrhage.

Treatment and Control: If possible, affected animals should be isolated from the rest of the herd and not fed a high-protein diet. Lesions should be examined to ensure they do not interfere with urethral patency. Clipping and cleaning hair around the prepuce may be beneficial. *C. renale* is usually sensitive to penicillins and cephalosporins, which may be beneficial if practical. Ulcerative posthitis is controlled

principally by limiting dietary protein to a level consistent with requirements. If untreated, scarring may be so severe that the penis cannot be extended.

ULCERATIVE BALANOPOSTHITIS AND VULVITIS

(Pizzle disease, Knobrot, Peestersiekte)

Ulcerative balanoposthitis and vulvitis is characterized by ulceration and inflammation of the glans penis and the prepuce, as well as the vulva of affected ewes. The first signs observed may be swelling and bleeding of the prepuce or vulva. On examination, ulcers are seen; these bleed readily when manipulated. In ewes, the ventral aspect of the tail (where it contacts the vulva) may be similarly affected. The condition may spread within a breeding

flock to involve a considerable proportion of the animals. The pregnancy rate in affected flocks is depressed.

The cause of ulcerative balanoposthitis and vulvitis is not clear. *Mycoplasma mycoides mycoides* has been isolated from affected sheep. *Trueperella* (*Arcanobacterium*) *pyogenes* is frequently present. In some cases *Histophilus ovis* has been isolated. Viruses, such as ovine herpesvirus 2 or, in the case of goats, caprine herpesvirus 1, may be involved.

Affected rams should be removed from the flock and isolated. If practical, affected ewes should also be maintained separately. Rams should be treated with antimicrobials; ewes also respond well to antimicrobial treatment. Irrigation of the prepuce may help prevent preputial adhesions. Tulathromycin has been used successfully. Recovered animals appear to have normal fertility.

POSTPARTUM DYSGALACTIA SYNDROME AND MASTITIS IN SOWS

Numerous etiologies or pathophysiologicals can be involved in this syndrome, which is reflected by the use of several different names—mastitis-metritis-agalactia (MMA) complex,agalactia syndrome, dysgalactia syndrome, mammary edema, periparturient hypogalactia syndrome,agalactia toxemia, and puerperal mastitis. However, these names are not synonymous and have often been misused. The syndrome can currently be classified according to the number of mammary glands affected, ie, uniglandular or multiglandular mastitis (including postpartum dysgalactia syndrome [PPDS], MMA complex). (See also MASTITIS IN LARGE ANIMALS, p 1358.)

Acute or chronic mastitis of only one or two mammary glands (acute or chronic uniglandular mastitis) in sows is present in nearly all herds. If the entire udder is acutely affected, it can be a primary or a secondary mastitis (acute multiglandular mastitis) as well as mammary edema ("hard udder syndrome"), which is common in primiparous sows.

Due to bacterial effects, acute multiglandular mastitis is usually accompanied by systemic signs andagalactia, whereas hard udder syndrome is not. Both conditions occur within the first 3 days after farrowing

and rapidly lead to piglet starvation.

Although the problem can be sporadic and limited to a few sows, sometimes it can occur in a greater number of sows and become nearly epidemic.

Differentiating acute multiglandular mastitis and hard udder syndrome can be difficult. For this reason, it is often reported by producers as "acute mastitis."

PPDS is characterized by transitory hypogalactia. It can lead to acute multiglandular mastitis and should be considered as the general cause of lactation failure in the sow. MMA complex is a misnomer and is only part of the more general PPDS. Although the mammary glands are swollen and frequently warmer than normal, grossly detectable primary mastitis is uncommon. Likewise, metritis (more commonly endometritis) is only an occasional finding in some herds. Finally, only rarely is there completeagalactia; most sows continue to produce milk but at a greatly reduced rate (hypogalactia or more correctly dysgalactia). The primary clinical signs of the sow's inability to produce a sufficient amount of milk to meet the needs of the piglets are growth retardation and increased mortality in piglets.

Mammary glands of sows are anatomically different from those of cows. In sows, there are no well-identified gland cisterns (gland sinus) in the mammary glands. There are usually two complete gland systems and two teat orifices per teat. When three orifices are present, one sinus ends blindly at the base of the teat and does not have glandular tissue. There is no muscular sphincter around the teat orifice. Therefore, intramammary treatment by way of the teat opening is impossible. Mammogenesis occurs almost exclusively during the last half of gestation and during the first days of lactation. New glandular tissues are produced during each gestation. For this reason, feeding and nutrition are of major importance during mammogenesis and the end of gestation, and are less important at midgestation.

Opinions differ as to whether the position of the caudal mammary glands should be considered as a risk factor for mastitis development. Most recent findings seem to reject an increased incidence in caudal glands compared with cranial ones.

Infection of a mammary gland during one lactation has no consequences for the next. However, chronic lesions of the teat canal may be present for multiple lactations.

ACUTE MULTIGLANDULAR MASTITIS

This syndrome is seen in all types of herds, including those with excellent hygiene and adequate disinfection practices. It occurs mainly during the first 3 days after farrowing and has major consequences for the piglets. Acute multiglandular mastitis can also follow a specific systemic disease of the sow (eg, septicemia, pseudorabies [see p 1300], porcine reproductive and respiratory syndrome [see p 729]).

Etiology and Pathogenesis: The etiology is multifactorial. Infections of the mammary gland are more often secondary, and many microorganisms have been identified, including *Escherichia coli*, *Klebsiella* spp, *Enterobacter* spp, *Citrobacter* spp, *Staphylococcus* spp (eg, *S. epidermidis*), and *Pseudomonas aeruginosa*. All these microorganisms are common in the environment of sows.

Although many sows in a herd may be severely affected, this type of mastitis is not contagious. After farrowing, the mammary gland is infected by environmental opportunist bacteria. Very few bacteria (often <100 organisms) are enough to colonize the mammary gland.

Major herd risk factors are the sow (PPDS, see below), the piglets (uncommon primary form), or the environment (eg, some beddings such as wood shavings can be contaminated by *Klebsiella pneumoniae*).

Some genetic lines of females are more resistant to coliform mastitis than others. The heritability of this characteristic is believed to be ~10%. Selection among the gilts to minimize or eliminate mastitis-prone sows can provide longterm improvement of the herd.

Clinical Findings: Systemic signs such as anorexia, constipation, fever, and depression are common. Local signs include acute induration of the mammary glands as well as severe edema and skin congestion of the mammary region. However, many sows (especially primiparous sows) develop mammary edema without any signs of acute mastitis. Circumstantial evidence suggests that this is usually associated with increasing milk production (often the milk drips during and right after farrowing) to such an extent that piglets are unable to consume all the available milk.

Once acute multiglandular mastitis is established, the secretion (with oxytocin) of milk is no longer possible. Affected sows deny piglets access to the teats by lying on their mammary glands. General signs result from bacterial multiplication and resorption of toxins. Common consequences for the litter include an economically significant increase in preweaning mortality caused by weak piglets, neonatal diarrhea, starvation, hypoglycemia-induced weakness, an increased incidence of crushing by the sow, and increased susceptibility to other diseases due to inadequate maternal immunoglobulin transfer and other problems (eg, runt pigs).

Diagnosis: Early diagnosis is not always easy. Most problem litters are thought to be due to early lactation problems. The primary differential diagnoses are peripartum mammary edema, which is often seen in primiparous sows without any systemic signs, and PPDS, which is less spectacular but affects a greater number of sows. A thorough physical examination, including careful palpation of the mammary glands, should be performed. However, it is necessary to be cautious in the interpretation—hard mammary glands without systemic signs do not always indicate acute mastitis. Although frequently seen, peripartum mammary edema is poorly documented. Sows often appear to be in

discomfort and lay down, as do sows with mastitis. However, peripartum mammary edema can certainly lead to an acute multiglandular mastitis. In contrast to the situation in cows, interpretation of cellular modifications in the milk is very difficult in sows.

Treatment and Control: Systemic antibiotic therapy should be started as soon as possible (see p 1376). Longterm control of a herd problem also requires identification and correction of risk factors. General antibiotic therapy as well as corticosteroids are useful to reduce the intensity of the inflammatory reaction. Meloxicam has also been shown to improve recovery of the sows. Management techniques to improve hygiene should be implemented as soon as possible. Cross-fostering is often the only effective way to save a litter.

ACUTE UNIGLANDULAR MASTITIS

In lactating or weaned sows, inflammation of a single mammary gland is common. Such uniglandular inflammations are more often noticed in old sows.

Etiology and Pathogenesis: The microorganisms involved are the same as those in acute multiglandular mastitis (see above). Sometimes only one or two mammary glands are affected; the cause should be identified. Traumatic lesions or inaccessibility of teats to piglets are common. Piglets suckling inguinal mammary glands of old sows are often unable to reach the teat during the phase of milk ejection. Usually, piglets have selected a specific gland by 24 hr after birth. A piglet suckling a teat affected by acute uniglandular mastitis will show growth retardation, while littermates remain healthy. Milk secretion may be restricted by acquired problems of mammary conformation (as in old sows), traumatic lesions, and other teat abnormalities. Teat lesions may have developed during the previous lactation, the previous weaning-to-estrus interval, or the previous gestation.

Teat damage as a result of trauma in a sow.
Courtesy of Dr. Glen Almond.

Diagnosis: The integrity of the mammary gland should be checked before each farrowing. Except for cases associated with inaccessible teats, risk factors involved in the development of blind teats should be identified. Traumatic teat lesions can be the consequence of injuries induced by piglets or other sows, or by slipping on slatted floors, etc. Unfortunately, these primary lesions often go unnoticed until several weeks or months have passed. Size homogeneity within a litter should also be monitored. Any discrepancy or growth retardation in a piglet compared with its littermate could be indicative of mastitis in a mammary gland.

Treatment and Control: The affected gland is lost for the current lactation and sometimes for the next lactation. During subsequent lactations, the number of nursing piglets should be limited, or the sow should be culled.

CHRONIC OR DRY-SOW MASTITIS

Postweaning or dry-sow mastitis is a common type of mastitis that affects one or a few glands. The prevalence among newly weaned sows is 10%–20%. Chronic mastitis is characterized by the formation of abscesses and granulomas in the mammary tissue, which are often seen at weaning or shortly after. A primary pathogen has not been identified. Bacteria commonly enter the mammary glands through teat wounds caused by the piglets' sharp teeth during suckling, fights among aggressive weaned sows grouped in the same pen, or trauma associated with the particular anatomy of inguinal mammary glands of old sows.

POSTPARTUM DYSGALACTIA SYNDROME

Postpartum dysgalactia syndrome (PPDS) is a primary cause of neonatal problems (eg, diarrhea, crushing, runting, inanition, poor growth) but is challenging to characterize because of its multiple manifestations and the difficulty in making an etiologic diagnosis. In a given herd, PPDS affects ~15%–20% of the sows; a higher percentage is uncommon. It is more common in young sows in their first or second parity.

Etiology and Pathogenesis: There are numerous multifactorial etiologies, which complicate the diagnosis and clinical evaluation. Classically perceived as a part of the mastitis-metritis-agalactia (MMA)

complex, PPDS should instead be considered a broader pathology. Thus, the MMA complex is essentially a subtype of PPDS, probably the most severe clinically but also the least common.

Evidence suggests that lipopolysaccharide (LPS) endotoxins, a portion of the cell wall of all gram-negative bacteria, play a central role. Bacterial endotoxins can be absorbed from the uterus (eg, endometritis or metritis), mammary glands (eg, acute multiglandular mastitis), or gut (eg, constipation as a consequence of feeding finely ground feed to sows can result in bacterial overgrowth and subsequent absorption of endotoxins from the intestines) and lead to endotoxemia. Identifying the source of the bacterial endotoxins is important to determine the best preventive approach for the particular herd.

The secretion of colostrum is determined by a complex hormonal balance (homeorhesis). LPS endotoxins exert their effects even before farrowing and act with the intervention of the innate immune system (macrophage activation). These changes adversely affect production and secretion of colostrum and milk. In addition, the colostrum is as important for its energy content as it is for its immunoglobulin content. Any decrease in the amount of ingested colostrum will result in consequences for the piglets such as diarrhea, inanition, and poor growth.

Other causes of general hypogalactia that should be considered include acute multiglandular mastitis, udder and teat abnormalities, hypocalcemia (uncommon in sows), and acute (agalactia) or chronic (hypogalactia) ergotism (uncommon in practice). Indeed, ergot derivatives suppress prolactin release.

Risk factors are those associated with stress of the sow and with conditions that lead to bacterial multiplication and subsequent endotoxemia. Such factors are numerous and are linked with different entities (eg, cystitis, metritis, vaginitis, constipation, mastitis).

Genetics can also be a risk factor for PPDS; most recent studies identified susceptibility genes on chromosome 17. Selection among genetic lines should include this parameter.

Clinical Findings: PPDS is seen almost exclusively within the first 3 days after farrowing. Associated signs are numerous and vary from herd to herd, as well as within herds. PPDS is commonly associated with fat sow syndrome, prolonged farrowings,

large litter sizes, and a high postpartum fever. Management practices reported in herds with a high incidence of PPDS include too much manual intervention during parturition or too many parenteral injections to sows (antibiotics, oxytocin, prostaglandins) or piglets (mainly antibiotics). Moving pregnant sows to the farrowing facilities ≤ 4 days before the expected farrowing, and feeding sows ad lib during lactation also should be considered risk factors. Piglet losses are due to emaciation or diarrhea (or both), as a consequence of poor nutrition during the first few days postpartum.

Diagnosis: Diagnosis is difficult and based on clinical signs. Clinical examination is best performed while piglets are nursing; milk ejection in affected sows is either absent or of brief duration, which causes the piglets to actively nurse for an extended time. During the initial stages, piglets repeatedly attempt to nurse at frequent intervals and do not settle after nursing. As a result of vigorous nursing efforts, the teats may be traumatized. As the energy reserves of the piglets are depleted, their attempts to nurse decrease, and they often migrate to the warmest portions of the farrowing crate. Crushing by the sow is common. Therefore, litter behavior should be watched closely for a prolonged time when trying to diagnose PPDS.

Mammary tenderness, swelling, and teat damage are consistent with a diagnosis of lactational insufficiency. The mammary glands vary from grossly normal to swollen, firm, and warm to the touch, sometimes with blotched purple skin. Pure bacterial cultures may be isolated from milk samples. Rectal temperature of the sow varies from normal to markedly increased ($>40.5^{\circ}\text{C}$ [104.9°F]). The concept that postpartum rectal temperatures $>39.5^{\circ}\text{C}$ (103.1°F) predict early lactation problems must be questioned. Physiologic hyperthermia observed in lactating sows should not be confused with fever. Reduced appetite or anorexia, constipation, and depression may also be seen. Abnormal and copious vaginal discharges may be seen in some sows (eg, cervicitis, endometritis). Cystitis, metritis, vaginitis, constipation, or mastitis in the sow and diarrhea in neonatal piglets should be considered as a general syndrome (requiring an overall diagnosis) rather than as individual problems.

Treatment and Control: Systemic or local therapeutic intervention (antibiotics, NSAIDs) can sometimes be helpful but only

on a short-term basis. Flunixin meglumine may help to counteract the effects of endotoxins. Antimicrobial treatment is usually prescribed before susceptibility can be tested. A broad-spectrum antibiotic is therefore recommended. However, if antibiotics are used longterm, a dependence on them for puerperal fevers, acute mastitis, vaginitis, endometritis, or neonatal diarrhea can develop rapidly and lead to multiresistant bacterial infections. Oxytocin or prostaglandins (or both) can be useful in cases of prolonged farrowing or postpartum endometritis. By far the most effective method is to cross-foster the piglets from affected to healthy sows, as long as the health status of the litters are equivalent. Oxytocin (5–10 U/sow) is occasionally effective in reestablishing lactation if used 4 or 5 times at 2- to 3-hr intervals. In herds in which PPDS is a significant problem, incidence may be reduced by inducing parturition with prostaglandin $F_{2\alpha}$; this results in rapid induction of labor and dilatation of the teats for a shorter period of time. However, the amelioration is not constant

among herds and depends on farm circumstances.

As many risk factors as possible should be identified and corrected or minimized. Systematic manual interventions during farrowing or uterine washings should be limited to only those that are necessary. There is no clear evidence that vaccines have a beneficial effect. Good sanitation tends to decrease the incidence of mastitis in the sow and diarrhea in the piglets, but PPDS is also common in herds in overall good health and with a high level of hygiene.

For chronic mastitis, use of partially slatted farrowing pens and cleaning with disinfectants between batches of sows in the farrowing and breeding areas may be helpful. Cutting or grinding the piglets' teeth after farrowing is not considered a good way to control chronic mastitis. Indeed, it can lead to a high prevalence of mastitis, possibly caused by changes in the oral flora of the piglets or the failure of piglets to suckle as a result of sore mouths from careless cutting of teeth.

PROLONGED GESTATION IN CATTLE AND SHEEP

Parturition is induced by the fetus in both cattle and sheep. It is initiated by rising cortisol levels in the fetus that provoke a cascade of endocrine activity in the dam. Fetal cortisol increases as a result of increased adrenocorticotrophic hormone (ACTH) production by the maturing fetal pituitary caused by fetal stressors such as hypoxia and hypercapnia. Gestation length is unique to each fetus, but approximate gestation lengths can be ascribed to each species (see TABLE 1, p 1324).

In cattle, gestation length is influenced by factors such as the breed of the cow and bull, calf gender, single vs multiple birth, the parity of the cow, and the fetal genotype. Environmental factors, including nutrition, ambient temperature, and the season of the year, have a smaller influence. The breed of cattle has the greatest influence on gestation length. In European cattle of the *Bos taurus* species, considerable breed variation is recognized (eg, 279 days mean gestation in Holstein-Friesian to 287 days in Charolais). In breeds of the *Bos indicus*

species, a slightly longer gestation length is often seen (eg, Zebu cattle have a mean gestation length of 296 days). Within breeds, individual bulls may sire calves with longer gestation length than normal, leading to a higher incidence of dystocia. In sheep, the normal gestation length is 144–150 days.

In many cases, prolonged gestation is incorrectly diagnosed because of human error. The service dates of dairy cattle are normally known. Hence the date of anticipated parturition is calculated and recorded once pregnancy is confirmed. In beef cattle, in which cows often run with a bull, exact calving dates are not known, but individual pregnant cows are expected to calve within a recognized calving season. Individual animals that have not calved at the anticipated time are checked to confirm they are still pregnant and that their pregnancy appears to be normal.

In sheep, the exact lambing date is seldom known unless ewes were served in hand or by artificial insemination. In most flocks the ewes run with rams and, when

served, receive a raddle crayon mark on their rumps to indicate that service has occurred. Crayon color is changed at 14- to 17-day intervals, and after later pregnancy confirmation, a lambing date within a 14- to 17-day period is calculated. Individual ewes that fail to lamb are culled or further evaluated for pregnancy.

Miscalculation of the prospective calving or lambing date, failure to record a subsequent service, faulty pregnancy diagnosis, and incorrect identification of animals may lead to a diagnosis of prolonged gestation in an animal that has a normal pregnancy. True prolonged gestation is relatively uncommon; the common denominator is a defective hypothalamic-pituitary-adrenal axis. Suspected cases should be investigated and examined with care. In some cases, the fetus is dead or severely deformed and is of little economic value. The life of the dam may be at risk if prolonged gestation is allowed to continue, and termination of the abnormal pregnancy is recommended.

Diagnosis: When a number of cases of prolonged gestation are seen in a herd or flock, a full investigation should be conducted in an attempt to identify the cause and possibly a preventive program. A genetic abnormality may be determined by a study of pedigrees or by finding an abnormal karyotype in affected fetuses. Possible exposure to toxic plants and viral infection should be investigated. Tests for evidence of pathogenic viruses or serologic evidence of exposure to them may lead to clear evidence of virus involvement. In some cases, the cause of prolonged gestation remains unknown. Evidence of pituitary hypoplasia or compromise may be found, but the underlying cause remains elusive.

Treatment: In a case of suspected prolonged gestation, the dam's breeding records, if available, should be checked to ensure that parturition truly is overdue. Treatment of a case in which gestation is not genuinely prolonged may result in the delivery of a premature fetus that is unlikely to survive. Once the true length of gestation is established, a full clinical examination of the dam should be conducted.

In cattle, rectal examination of the uterus and its contents is an important diagnostic aid. Fetal parts may be palpable, and in some cases it is possible to detect an abnormal cranium. An ultrasonographic scan may confirm the presence of fetal abnormalities, including a thin-walled, fluid-filled cranium. The weight of an overdue fetus may cause it to pass under

the rumen while still within the uterus, so that it cannot be palpated per rectum.

In some animals, prolonged gestation is accompanied by development of excessive amounts of fetal fluid. The origin of excessive fetal fluid can be assessed by analysis of sodium and chloride levels in an aspirated sample. Amniotic fluid contains sodium at ~120 mmol/L and chloride at ~90 mmol/L. Allantoic fluid contains sodium at 50 mmol/L and chloride at 20 mmol/L. The correlation between hydrops amnion and hydrops allantois and prolonged gestation is tenuous, however. Most fetal giants suffer from oligoamnios.

In true prolonged gestation, the fetus is unlikely to be of any economic value. Treatment should be aimed at fetal delivery with minimal damage to the dam. In cases of fetal giantism, the dam may be distressed by the weight of the fetus and its associated fluids. Painful edema in front of the udder may indicate rupture or impending rupture of the prepubic tendon. A canvas sling support can be placed around the abdomen to prevent further damage until the pregnancy is terminated. General health of the dam should be assessed and economic considerations discussed with the owner before treatment is attempted. Milk production may be compromised.

Successful induction of parturition requires an intact fetal hypothalamic-pituitary-adrenal axis. Pregnancy is maintained in cases of prolonged gestation chiefly by continued production of progesterone by the corpus luteum. Spontaneous induction of birth in cases of prolonged gestation fails as a result of insufficient production of fetal cortisol and the failure of luteolysis to occur. Birth in both cows and sheep can be successfully induced by administering both prostaglandin $F_{2\alpha}$ (or its synthetic analogue cloprostenol) and the corticosteroid dexamethasone by IM injection. Luteolysis is induced by the prostaglandin, and the maternal hormone cascade that precedes parturition is initiated by the corticosteroid. In cows, 500 mcg cloprostenol and 20 mg dexamethasone are given; in sheep 125 mcg cloprostenol and 16 mg dexamethasone are recommended. A single dose of these two drugs is normally effective. Parturition should begin in 24–72 hr.

Induced parturition should be monitored carefully. Assistance may be required if there is evidence of uterine inertia or damage to the abdominal wall, either of which might make expulsive efforts ineffective. Fetal malposition requiring obstetric assistance may occur once birth begins. If the fetus is very large, dystocia

due to fetal-pelvic disproportion may occur, and assisted delivery by careful traction may be attempted. If this is not possible, cesarean section may be required. If the dam is seriously ill but considered well enough to withstand surgery, an elective cesarean without an attempt at vaginal delivery may be considered. Fetal dystocia can be a problem, especially in very valuable cloned offspring, and intensive care facilities may be needed.

After fetal delivery, uterine involution may be encouraged by administration of oxytocin. Retention of fetal membranes is managed in the usual way (*see* p 1381). Fluid therapy, antibiotics, and treatment with NSAIDs such as flunixin meglumine may aid recovery and provide analgesia.

PROLONGED GESTATION ASSOCIATED WITH FETAL DEATH

Fetal death may be followed by abortion, fetal maceration, or fetal mummification. In cases of abortion and fetal maceration, the hormonal support of pregnancy is lost. The animal normally shows signs that pregnancy has terminated. An aborted fetus may be found, the dam may show an abnormal vaginal discharge, and she may return to estrus. Fetal bones may be trapped in the uterus and compromise future breeding.

In cases of fetal mummification, fetal death is often not immediately apparent. In such cases, the corpus luteum persists in the ovary, and there is no vaginal discharge and no signs of estrus. The abnormal pregnancy in such animals continues indefinitely. Affected animals are normally identified when owners notice that external signs of late pregnancy, including abdominal enlargement, are less obvious than in other members of a group. Clinical examination reveals that the fetus is dead, although the dam is pregnant. Rectal examination reveals an irregularly shaped, contracted uterus with a fetal mass but no fetal fluid within it. There is no fremitus in the uterine artery. Ultrasonographic examination of accessible parts of the uterus per rectum confirms the diagnosis. The abnormal pregnancy can be terminated by a single IM injection of prostaglandin $F_{2\alpha}$. The fetus is expelled from the uterus and can be manually removed from the vagina 48 hr later.

In sheep, fetal mummification can be diagnosed by abdominal palpation supported by a transabdominal ultrasonographic scan. Affected animals are normally culled on economic grounds. Treatment can be attempted (*see* above).

PROLONGED GESTATION ASSOCIATED WITH FETAL DEFORMITY

Prolonged gestation associated with fetal deformity cases usually occur as the result of some compromise of the hypothalamic-pituitary-adrenal axis of the fetus, which is no longer able to initiate parturition. The affected fetus may either die and be aborted or live on indefinitely in the uterus. Genetic, infectious, toxic, and unknown causes have been associated with this problem.

Genetic Abnormalities: Prolonged gestation associated with fetal adrenal malfunction is a genetically determined prolonged gestation caused by an autosomal recessive gene of the fetus in Holstein-Friesian cows. The fetal adrenal glands fail to produce corticosteroids at term, in response to fetal ACTH. As a result, the fetus continues to grow until it outgrows its blood supply. Induction with dexamethasone does not induce normal labor and parturition because of insufficient preparation of the birth canal. A cesarean section will save the dam, but the fetus invariably dies due to adrenal insufficiency.

Four further genetic abnormalities associated with prolonged gestation in various breeds of cattle involve fetal pituitary abnormalities. In one condition, severe fetal oversize (fetal gigantism) is present. In the second, the calf has severe craniofacial defects and is much smaller than normal. In the third condition, multiple skeletal abnormalities are present. In a fourth condition, genetic abnormalities may occur as a result of cloning.

Prolonged gestation and fetal gigantism has been reported in Holstein-Friesian, Ayrshire, and Swedish breeds of cattle. Gestation is prolonged by 21–150 days. Pronounced abdominal enlargement is seen in some cases. There is no attempted parturition unless the fetus dies first after having outgrown its blood supply. Cervical relaxation is poor, and dystocia invariably results. The calf weighs 48–80 kg at birth and shows signs of postmaturity. The coat and hooves are longer than normal, and prominent loose teeth are present in the gums. Breathing is difficult as a result of failure of surfactant release, and the calf may die from hypoglycemia. At necropsy, hypoplasia of the anterior pituitary and adrenal glands is seen.

Prolonged gestation with craniofacial defects in the fetus has been reported in

Holstein-Friesian, Ayrshire, Guernsey, and Jersey breeds of cattle and is thought to be caused by a recessive gene. Affected fetuses cease to grow at 7 mo gestation. There is no spontaneous parturition in affected cattle because of the nonfunctional or absent pituitary gland in the fetus. Calves are usually dead when delivered. Some may show evidence of severe abnormalities of the cranium and face.

Prolonged gestation associated with multiple skeletal abnormalities has been reported in Hereford cattle. Affected calves show evidence of pituitary aplasia or hypoplasia. Arthrogryposis, torticollis, kyphosis, and scoliosis are present, and some calves have cleft palates.

Prolonged gestation associated with cloning has been reported in both fetal calves and lambs produced by somatic cell nuclear cloning. Early placental abnormalities have been detected in a high proportion of such animals, and placentomegaly may be seen in later pregnancy. The abnormality may result in fetal death or, if the fetus survives, in the large offspring syndrome. Spontaneous birth may not occur, and prolonged gestation results. Fetal lung and maternal mammary development is retarded and can compromise fetal survival.

Infectious Causes: Although bovine viral diarrhea virus (see p 267) can cause abortion in cattle, it can also produce congenital defects in the fetus. These include cerebellar hypoplasia, anencephaly, and hydrocephaly. Affected calves may be born with severe defects of the CNS, but prolonged gestation occasionally occurs if pituitary function is compromised. The related pestivirus border disease virus (see p 622) can produce severe brain and coat abnormalities in fetal lambs. Pituitary compromise in such lambs can lead to prolonged gestation.

Akabane virus (see p 620), found in Africa, Australia, the Middle East, and the Far East, can be transmitted by insects to both pregnant cattle and sheep. Bovine fetuses exposed to the virus at 76–104 days gestation may develop hydranencephaly (fluid-filled cavitation of the brain). Exposure to the virus at 105–174 days of pregnancy may cause both hydranencephaly and arthrogryposis. Affected fetuses may have severe brain damage. The cerebral cortex may be absent and the cranial cavity filled with fluid. Cerebellar hypoplasia may be

present, and the brain stem is smaller than normal. Compromise of pituitary function in the affected fetus can lead to prolonged gestation.

Bluetongue virus (see p 738), found in Africa, Australia, North and South America, and Europe, is also transmitted by insects; infection can occasionally cause prolonged gestation. The fetuses of cows exposed to the virus at 60–120 days of pregnancy developed hydranencephaly, whereas fetuses exposed later in pregnancy developed less severe CNS defects.

Gestation lengths >200 days have been recorded in ewes vaccinated during pregnancy with Rift Valley fever attenuated viral vaccine. Affected lambs developed severe brain defects and skeletal abnormalities. Some ewes developed hydrops amnion by the fourth month of gestation. Ewes in which pregnancy was not terminated developed ketosis.

Toxic Causes: Several plant toxins cause fetal deformity and prolonged gestation when eaten accidentally or fed experimentally. When fed to sheep in early pregnancy, *Veratrum californicum* (skunk cabbage) produces fetal deformities, gigantism, and prolonged gestation. Cranial defects and brain and eye abnormalities were seen in fetuses of ewes fed this plant at 14 days of gestation; pregnancy length in some cases was >230 days. The plant contains the amine cyclopamine, which is believed to be responsible for the fetal abnormalities. This plant also contains a number of toxic alkaloids that cause GI disturbance, dyspnea, and convulsions in sheep. *Veratrum album* has similarly caused prolonged gestation and fetal abnormalities in Holstein-Friesian cows in Japan.

An unidentified toxin in the plant *Salsola tuberculatiformis* (cauliflower saltwort) is thought to cause prolonged gestation in sheep. Pregnancy was extended >220 days, and affected lambs showed atrophy of the pituitary, adrenal, and thyroid glands. Fetuses appear to be most susceptible to the toxin in the first and third trimesters of pregnancy. Amniotic fluid continues to increase in volume in cases of prolonged gestation associated with this plant. Physical abnormalities such as cleft palate prevent normal swallowing of amniotic fluid in affected fetuses. Excessive fetal weight and the weight of accumulated fetal fluids may lead to rupture of the prepubic tendon in ewes.

PSEUDOPREGNANCY IN GOATS

Pseudopregnancy is one of the major causes of anestrus in dairy goats during the breeding season. Older, parous does are most often affected. It is characterized by the persistence of a corpus luteum in the absence of a (viable) conceptus in the uterus.

Etiology and Pathogenesis: Failure of luteal regression, either in nonmated cycling animals or in mated does affected by embryonic or fetal mortality, is the key factor in the pathogenesis of the disorder. Pseudopregnancy can also spontaneously develop in unmated animals, even during the nonbreeding season. A genetic predisposition has been postulated, but in a recent study from the UK the incidence of pseudopregnancy in the offspring of affected dams was not significantly different from that in daughters of unaffected does.

Clinical Findings: Hydrometra (accumulation of fluid in the uterus) is the primary clinical feature of pseudopregnancy. It develops during prolonged and continuous exposure to progesterone from the corpus luteum. When not diagnosed, pseudopregnancy can persist for up to several months, and the amount of fluid can reach a volume of several liters. In such cases the distended abdomen will give the false impression that the animal is pregnant; this can also be accompanied by udder enlargement.

Diagnosis: Pseudopregnancy can be diagnosed by ultrasonography. The fluid is recognized as anechoic, black spots of

variable size, separated by thin, double layers of tissue that represent sections through the apposing walls of the distended, curved uterine horns. When an abundant amount of fluid is present, these tissue layers can be seen undulating when the examiner shakes the abdominal wall of the doe. During an early ultrasonographic pregnancy diagnosis (20–30 days after mating or insemination), it can be difficult to discriminate between a normal pregnancy and a hydrometra because the embryo or placentomes can be difficult to locate at that stage, and excess fluid may be mistaken for allantoic fluid.

Treatment and Prognosis: Treatment with a luteolytic dose of prostaglandin $F_{2\alpha}$ (or one of its synthetic analogues) induces luteal regression and discharge of the uterine fluid within 1–2 days. If treated during the breeding season, the doe will come into estrus within 2–3 days and can be mated or inseminated again. Sometimes a second injection is necessary to accomplish a complete emptying of the uterus. Pseudopregnancy also may end spontaneously when progesterone production by the (aging) corpus luteum stops. As a result, relaxation of the cervix and stimulation of uterine contractility occur, followed by discharge of the uterine fluid. This latter process has also been described as “cloudburst.” The fertility of does appears to be normal after effective treatment with prostaglandins, so culling of affected goats is generally not indicated.

RETAINED FETAL MEMBRANES IN LARGE ANIMALS

(Retained placenta)

COWS

Retention of fetal membranes, or retained placenta, usually is defined as failure to expel fetal membranes within 24 hr after parturition. Normally, expulsion occurs within 3–8 hr after calf delivery. The incidence in healthy dairy cows is 5%–15%,

whereas the incidence in beef cows is lower. The incidence is increased by abortion (particularly with brucellosis or mycotic abortion), dystocia, twin birth, stillbirth, hypocalcemia, high environmental temperature, advancing age of the cow, premature birth or induction of parturition, placentitis, and nutritional disturbances.

Cows with retained fetal membranes are at increased risk of metritis, displaced abomasum, and mastitis.

Retention of fetal membranes is mediated by impaired migration of neutrophils to the placental interface in the periparturient period. The impaired neutrophil function extends into the postpartum period and probably mediates the recognized complications of retained fetal membranes. Cows with retained fetal membranes have increased cortisol and decreased estradiol concentrations in late pregnancy. They may also have an altered prostaglandin (PG) E_2 :PGF $_2$ ratio. Uterine contractility is increased in affected cows. (Placental detachment, rather than uterine motility, is responsible for retention of fetal membranes.)

Diagnosis is usually straightforward as degenerating, discolored, ultimately fetid membranes are seen hanging from the vulva >24 hr after parturition. Occasionally, the retained membranes may remain within the uterus and not be readily apparent, in which case their presence may be signalled by a foul-smelling discharge. In most cases, there are no signs of systemic illness. When systemic signs are seen, they are related to toxemia. Uncomplicated retention of fetal membranes is unsightly and inconvenient for animal handlers and milkers but generally not directly harmful to the cow. However, cows with retained fetal membranes are at increased risk of developing metritis, ketosis, mastitis, and even abortion in a subsequent pregnancy. Cows that have once had retained fetal membranes are at increased risk of recurrence at a subsequent parturition.

Manual removal of the retained membranes is not recommended and is potentially harmful. Trimming of excess tissue that is objectionable to animal handlers and contributes to gross contamination of the genital tract is permissible. Untreated cows expel the membranes in 2–11 days. Routine use of intrauterine antimicrobials has not been found to be beneficial and may be detrimental. Although advocated at various times, oxytocin, estradiol, PGF $_{2\alpha}$, and oral calcium preparations have not been shown to hasten expulsion of retained membranes or to prevent complications. When systemic signs of illness are present, systemic treatment with antimicrobials is indicated. In herds in which incidence of retained fetal membranes is unacceptably high, predisposing causes should be sought and eliminated. Supplementation with vitamin E and selenium for herds in which these nutrients are deficient has been found to be beneficial.

MARES

Equine fetal membranes are normally expelled within 3 hr after parturition, but expulsion may be delayed for 8–12 hr or even longer without signs of illness. The cause of retention of fetal membranes often is not known, but the condition is associated with infection, abortion, short or prolonged gestation, uterine atony, and dystocia. Mares that have retained their fetal membranes appear to be at increased risk of recurrence of the condition, and Friesian mares are particularly predisposed. Retention of just a portion of the fetal membranes entirely within the uterus (usually at the tip of the previously nongravid uterine horn) is less conspicuous but equally likely to result in complications. For this reason, the chorionic surface of the expelled membranes should be examined carefully to ensure they have been completely expelled.

Retention of fetal membranes may mediate development of metritis or even peritonitis. Laminitis is a potential sequela. For these reasons, it is common practice to administer oxytocin (5 U, IM, every 2–3 hr) beginning 3–4 hr after parturition if the membranes have not yet been expelled. Calcium supplementation may be beneficial. Manual removal of retained membranes carries the risk of uterine damage or prolapse and is not recommended beyond gentle tugging to displace already loosened membranes. In cases of prolonged retention of fetal membranes, antimicrobials should be administered prophylactically, along with other therapeutic strategies aimed at preventing laminitis (*see* p 1109). Mares that have recovered from retention of fetal membranes do not generally have lower fertility.

DOES, EWES, AND SOWS

In does and ewes, the incidence of retained fetal membranes increases with larger litter sizes and with assisted parturition. Systemic treatment to guard against infection and gentle traction on exposed membranes may be used. In sows, retained placentae are contained within the uterus and are not visible at the vulva. In this species, entire fetuses may be retained. Usually, the fetus or membranes decompose in situ. This may be accompanied by signs of systemic illness and a purulent vaginal discharge. Although serious or fatal sequelae occasionally occur, the prognosis for recovery and future fertility is surprisingly good. Antimicrobial treatment is indicated in animals with systemic signs of illness.

SEMINAL VESICULITIS IN BULLS

The seminal vesicles are paired accessory sex glands located on the floor of the pelvis, lateral to the ampullae, and dorsal to the neck of the urinary bladder. The vesicles secrete a clear fluid that adds volume, nutrients, and buffers to semen. The term "seminal" vesicle is a misnomer, because the vesicles are not a reservoir for spermatozoa.

Seminal vesiculitis is an inflammation and often an infection of one or both vesicular glands. The purulent material associated with vesiculitis is a contaminant of semen and is a cause for semen to be discarded from bulls collected at an artificial insemination center. Bulls found to have vesiculitis during a breeding soundness examination are considered unsatisfactory breeders. Bulls refractory to treatment efforts should be culled.

Epidemiology: Vesiculitis has been reported in bulls wherever breeding cattle are raised. The reported incidence of vesiculitis in the general population of bulls is 1%–10%. However, incidences of 20% and even 49% have been reported for bulls housed in groups. Bulls of all ages can be affected, but vesiculitis is most frequently seen in yearling bulls presented for a breeding soundness examination or collected for the first time. Because many yearling bulls affected with vesiculitis are culled, it is seen less frequently in adult bulls.

Etiology and Pathogenesis: Vesiculitis is typically considered to be caused by bacterial infection. The most commonly identified bacteria are *Trueperella pyogenes*, *Pseudomonas aeruginosa*, streptococci, staphylococci, *Proteus* spp, and *Escherichia coli*. Other microbial agents implicated include *Mycoplasma bovis*, *Chlamydia* spp, and viruses.

Postulated pathogenic mechanisms include infectious agents ascending the urethra to the vesicle, descending through the ductus deferens from the testicles or epididymides, or metastasis from another tissue or organ hematogenously. The ascending route of infection is considered unlikely unless the bull has accompanying penile trauma or urethritis. The descending route would be considered if the vesiculitis is ipsilateral to an infectious epididymitis or orchitis. Vesiculitis subsequent to systemic infection, umbilical infection, infectious

arthritis, or pneumonia is considered more plausible.

Congenital malformation of the excretory ducts of the vesicles where they open into the urethra at the colliculus seminalis has been reported. A malformation of the excretory duct orifice permits reflux of spermatozoa or urine from the pelvic urethra into the vesicle. If the tubular lining of the vesicle degenerates subsequent to irritation from abnormal material in the ducts, significant local inflammation can result. This noninfectious etiology may account for the poor therapeutic response in some cases.

Clinical Findings: There are usually no external signs of disease. It has been suggested that a bull with a severe acute case or vesicle abscessation may stand with its back arched, have pain on defecation or rectal examination, and show hesitation when mounting. However, such clinical signs are very uncommon.

Diagnosis: Vesiculitis is usually first suspected after collection of a semen sample grossly contaminated with purulent material. If the bull has vesiculitis, the rectal examination typically reveals an enlarged, sometimes irregular, and often fibrotic vesicle. Vesiculitis may be unilateral or bilateral. If vesiculitis is unilateral, there is usually asymmetry in the size of the glands. Infrequently, a vesicle will be abscessed; in such cases, the affected vesicle is markedly larger than the other and may be fluctuant on palpation.

Purulent contamination of semen is not pathognomonic for vesiculitis. A bull with epididymitis, orchitis, or posthitis may also have semen contaminated with purulent exudate. The entire genital tract must be examined to determine a possible cause for the abnormal semen. The prepuce may need to be douched with water or saline before collection of semen to exclude posthitis as a transient cause of pus in semen. Semen may be cultured but, unless collected aseptically after catheterization of the urethra, culture is usually unrewarding because of microbial contamination from the prepuce.

Treatment and Prognosis: Because vesiculitis may have a bacterial etiology, broad-spectrum antibiotics administered at labeled therapeutic dosages are usually

administered to affected bulls. There are no published controlled studies that indicate preference of a specific antibiotic for treatment. Prolonged-release antibiotics are preferable because the bull, which can become unruly, does not have to be handled daily. Because vesiculitis is an inflammation as much as an infection, NSAIDs reduce the excretion of purulent material. Transient alleviation of purulent contamination may be achieved during the treatment interval in some bulls, but the prognosis for a longterm

cure is guarded to poor. This is particularly true for chronic cases. Spontaneous remission has been seen when vesiculitis was diagnosed in bulls <1 yr old. Semen contaminated with purulent material is not suitable for artificial insemination and should be discarded. Surgical removal of affected vesicles has been done but is a difficult procedure. The prognosis after surgery is fair in yearling bulls; surgery has not been successful in adult bulls with chronic vesiculitis.

TRICHOMONIASIS

Trichomoniasis is a venereal disease of cattle characterized primarily by early fetal death and infertility, resulting in extended calving intervals. Distribution is probably worldwide.

Etiology and Epidemiology: The causative protozoan, *Tritrichomonas foetus*, is pyriform and ordinarily 10–15 × 5–10 μm, but there is considerable pleomorphism. It may become spherical when cultured in artificial media. At its anterior end, there are three flagella approximately the same length as the body of the parasite. An undulating membrane extends the length of the body and is bordered by a marginal filament that continues beyond the membrane as a posterior flagellum. Although *T. foetus* can survive the process used for freezing semen, it is killed by drying or high temperatures.

T. foetus is found in the genital tracts of cattle. When cows are bred naturally by an infected bull, 30%–90% become infected, suggesting that strain differences exist. Variation in breed susceptibility to trichomoniasis may also exist. Bulls of all ages can remain infected indefinitely, but this is less likely in younger males. By contrast, most cows are free of infection within 3 mo after breeding. However, immunity is not longlasting and reinfection does occur. Transmission can also occur when the semen from infected bulls is used for artificial insemination.

Clinical Findings: The most common sign is infertility caused by embryonic death. This results in repeat breeding, and attending stock persons often note cows in heat when they should be pregnant. This,

along with poor pregnancy test results (eg, too many “nonpregnant normal” and late-bred cows) is usually the presenting complaint. In addition to a reduced number of cows estimated to calve during the regular calving season, an increased number of cows with a “nonpregnant abnormal” reproductive tract diagnosis is seen. These include cows with pyometra, endometritis, or a mummified fetus.

Fetal death and abortions can also occur but are not as common as losses earlier in gestation. *T. foetus* has been found in vaginal cultures taken as late as 8 mo of gestation and, apparently, live calves can be born to infected dams. Pyometra occasionally develops after breeding.

Diagnosis: History and clinical signs are useful but are essentially the same as those of bovine genital campylobacteriosis (see p 1347). Confirmation depends on isolation of *T. foetus*, which may be difficult to differentiate from other trichomonads resident in the digestive tract. Diagnostic efforts are directed at bulls, because they are the most likely carriers. Suction is applied to a pipette while it is used to vigorously scrape the epithelium in the preputial fornix. Alternatively, douching with saline or lactated Ringer's solution (without preservatives) can be used. Aspirates or douches, concentrated by centrifugation, are examined using darkfield contrast microscopy. This material is also transferred immediately to the surface of a liquid culture medium such as Diamond medium. Better success culturing the organism has been reported when using commercially available media-filled pouches. In addition, incubating the media

beyond the standard 48 hr may also enhance the accuracy of the diagnosis. Sampling every 48 hr for 10 days from the bottom of the tube and examining at 100–400× may reveal the rolling jerky movements of *T. foetus*. Studies have examined the possibility of using PCR assays to identify *T. foetus* directly from the preputial samples without an intervening culture. These tests are being used by some laboratories to reduce the time required for a definitive diagnosis of trichomoniasis. Some diagnostic laboratories are suggesting that the scraping be placed in phosphate buffered saline before transport to the diagnostic laboratory. A sample prepared in this way can be effectively examined for both trichomoniasis and campylobacteriosis by using a specific PCR application.

Studies suggest that 90%–95% of infected bulls will be positive on culture, and that three successive cultures at weekly intervals will detect ~99.5% of infected bulls. A vaginal discharge (after treatment of pyometra) or vaginal mucus (obtained toward the end of a luteal phase) may also be of diagnostic value.

The number of times the bull battery should be sampled and cultured to ensure the bulls are negative depends on the prevalence of fetal wastage in the cow herd. With more open and late cows, the frequency of testing should increase to improve the probability that bulls are negative for the protozoan.

Treatment and Control: Various imidazoles have been used to treat bulls, but none is both safe and effective. Iprnidazole is probably most effective but, due to its low pH, frequently causes sterile abscesses at injection sites. In addition, bulls are probably

susceptible to reinfection after successful treatment. Resistance to ipronidazole may also be a concern. The biggest problem, however, is that the success of treatment is measured by repeated sampling, which may mean the individual bull can never be definitively called negative. Therefore, an unqualified recommendation for the bull's use cannot be given.

Control consists of eliminating the infection from the bull battery by culling all bulls and replacing them with virgin bulls or by testing and culling positive bulls. Repeated testing in older bulls may be unsatisfactory, and it may be prudent to cull them all. Reinfection is prevented by exposing only the uninfected (clean) bulls to uninfected (clean) cows. Clean cows are assumed to be those with calves at foot (even though some infected cows may produce a live calf) and virgin heifers. In situations in which several herds are commingled on the same range, caution must be exercised to ensure that cows and heifers are not exposed to potentially infected bulls at the home ranch before they are turned out on the common grazing pasture.

T. foetus can be safely eliminated from semen with dimetridazole.

Vaccines developed some time ago for use in cows and evaluated in the field were not highly effective, especially in the absence of other control measures. However, the efficacy of whole-cell *T. foetus* vaccines has recently been critically reviewed. Although there is some evidence to suggest that timely vaccination will improve reproductive performance in heifers, there is a distinct lack of evidence that vaccination will reduce "bull-associated outcomes."

UDDER DISEASES

See also MASTITIS IN LARGE ANIMALS, p 1358, and PSEUDOCOWPOX, p 868.

DISEASES OF BOVINE TEATS AND SKIN

Bovine Ulcerative Mammillitis (Bovine Herpesvirus II and IV): Bovine herpesvirus II and IV (BHV-II, BHV-IV) can cause an acute, ulcerative condition of teat and

udder skin of dairy cows that is often referred to as bovine ulcerative mammillitis. BHV-II can occur sporadically or in outbreaks that often have a seasonal association with cold weather and may result in reduced milk production and increased susceptibility to bacterial mastitis.

Clinical signs range from relatively mild, small plaques of edema to severe ulceration. Early signs may vary, but the

lesions often begin as one or more thickened, edematous plaques of varying size on the skin of one or more teats. Vesicles develop and may rapidly rupture, leaving a raw, ulcerated area that becomes covered with a dark-colored scab. The scabs tend to crack and bleed, especially if milking is attempted. The lesions are of variable size and can include much of the teat wall and orifice. Teats are generally painful, and affected cows often resist milking, leading to development of mastitis. The greatest incidence is often seen in first-lactation cows, but previously unexposed cows of any age are susceptible. Severe lesions may take several weeks to heal.

Diagnosis is based on clinical signs and confirmed by histopathology or by virus isolation from early lesions. Treatment is directed toward supportive care, because there is no effective therapy for this virus. The use of iodophore-containing teat dips with added emollients may help to inactivate the virus. It is important to isolate affected cows and to use separate milking equipment. Affected animals should be segregated to prevent spread among all animals. The use of separate milking equipment; clean, single-use towels to dry udders; and clean gloves for milking personnel help to prevent spread of the agent to susceptible animals.

Pseudocowpox: Pseudocowpox is a condition of teat skin caused by a poxvirus that results in a characteristic horseshoe-shaped lesion or scab (*see* p 868).

Bovine Warts (Bovine Papillomavirus):

Several strains of bovine papillomavirus (BPV1, BPV5, BPV6, BPV9) cause the development of papillomas or fibropapillomas on teats. In some herds, pale, smooth, raised lesions develop frequently on teat skin and may persist indefinitely without causing problems. In other instances, filamentous or frond-like lesions develop at the teat orifice and interfere with milking. Bovine warts are spread by direct or indirect contact, and bovine papillomavirus DNA has been identified in blood, milk, urine, and other biologic fluids obtained from infected animals. Diagnosis is usually made presumptively based on examination of the lesion and exclusion of other causes. In many instances, treatment of warts is not necessary, but frond-like lesions that interfere with milking may require excision. The use of autogenous vaccines and virucidal teat dips may be recommended in herd outbreaks.

Teat-end Hyperkeratosis: The development of raised smooth or rough rings at the teat ends of lactating cows is a common occurrence and is associated with the keratin dynamics of the streak canal. Teat ends affected with hyperkeratosis may progress from smooth, doughnut-shaped lesions that do not affect milking to severely hyperkeratotic rings with radial cracks. When teats are severely affected, the ability to properly sanitize teat ends before milking may be compromised. Diagnosis is usually made by clinical examination of affected teats. The degree of hyperkeratosis is often characterized by scoring teat ends using the following scale: 1) no ring, 2) smooth ring, 3) rough ring, and 4) very rough, cracked ring.

The cause of hyperkeratosis is multifactorial; thus, prevention is directed toward a number of potential risk factors. Hyperkeratosis is often associated with cold weather, probably because of changes in peripheral circulation. Risk factors for development of hyperkeratosis include incorrect use of teat sanitizers, exposure of wet teats to cold weather, improper milking machine settings leading to overmilking, inadequate massage phase during milking, and inadequate milk letdown. After underlying risk factors are addressed, affected teats generally recover over several weeks or over a dry period.

Dermatitis: Dermatitis of the udder has a number of causes, including chemical irritants, sunburn, and bacterial infection. The udder can be exposed to chemical irritants from bedding additives (eg, some types of limestone) or chemicals used during milking. The irritation usually resolves after removal of the offending substance, but gentle udder washes and use of emollient products can accelerate healing. Udder impetigo (udder acne) is a bacterial dermatitis characterized by development of small pustules on the skin of the udder and teats. Staphylococci usually can be isolated from the pustules. Treatment of udder impetigo consists of clipping hair from the affected area and washing the skin thoroughly each day until the condition resolves.

Frostbite: Teat skin can chap and crack when wet teats are exposed to cold winds or frozen bedding areas. Exposure of wet skin to subfreezing temperatures may result in frostbite. Skin affected by frostbite becomes swollen and discolored and ultimately develops a leathery texture. In severe cases, the teat skin may slough. Frostbite is best prevented by ensuring that

teat skin is dry before allowing cows access to housing areas or pastures during periods of temperatures <0°F. Care should be taken to ensure that all bedding areas that contact teat and udder skin are thoroughly dry. Teat disinfectant products (eg, powder teat dips and other cold weather formulations) specifically designed for extremely cold weather are relatively successful at preventing frostbite after dipping. When liquid dips are used during periods of extremely low ambient temperatures, the teats should be dried before the cows exit the milking facility.

Udder Sores (Necrotic Dermatitis):

Moist, foul-smelling, necrotic lesions may develop in areas of tightly adjacent skin of some animals (such as the udder cleft). In heifers, the lateral aspect of the udder and medial aspect of the thigh are often involved. In this area, the udder is pressed tightly against the leg, resulting in chafing, dermatitis, and necrosis. Udder edema is a risk factor for development of this condition and must be treated concurrently. The necrotic skin should be cleaned daily with an antiseptic solution and thoroughly dried. Mild astringents should be applied. A similar condition, which may be associated with infestation by *Sarcoptes* mites, has been seen at the anterior portion of the udder between the two forequarters. Older cows have been reported to be at greater risk than heifers. The swollen, necrotic area may be treated topically with an approved niticide; however, appropriate milk withholding periods must be observed.

PHYSIOLOGIC DISORDERS

Udder Edema: Udder edema is common in high-producing dairy cattle (especially heifers) before and after parturition. Predisposing causes include age at first calving (older heifers are at greater risk), gestation length, genetics, nutritional management, obesity, and lack of exercise during the precalving period. Prepartum diets that contain excessive salt increase the severity of udder edema. Physiologic edema is not usually painful and occurs when pitting edema develops symmetrically in the udder before parturition. Udder edema is a risk factor for development of clinical mastitis and occasionally can become a chronic condition that persists throughout lactation. Treatment should be initiated if swelling threatens the udder support apparatus or if edema interferes with the ability to milk the cow. Edema can be treated by milking cows before

parturition. Positive effects of premilking in heifers have been reported, but the practice may predispose older cows to parturient paresis (see p 988). Massage, repeated as often as possible, and hot compresses stimulate circulation and promote edema reduction. Diuretics have proved highly beneficial in reducing udder edema, and corticosteroids may be helpful. Products that combine diuretics and corticosteroids are available for treatment of udder edema.

Precocious Mammary Development:

Initiation of milk secretion in heifers before calving is occasionally noted. Precocious mammary development in a single gland sometimes results from suckling by herdmates. Symmetric mammary development has been occasionally associated with ovarian neoplasia or exposure to feedstuffs containing estrogen or contaminated by mycotoxins. Removal of contaminated feedstuffs generally results in resolution of the problem.

Failure of Milk Ejection (Milk Let-down):

In rare instances, newly calved heifers may have problems with milk ejection. Fear of handling or unfamiliarity with the milking facility or milking procedures is the usual cause. Care should be taken to ensure that animals are handled calmly and gently and that the milking routine provides for adequate stimulation (>20 sec) before attaching the milking unit. Administration of oxytocin (20 IU, IM) may be necessary in some instances, but doses should be gradually reduced to avoid dependence on administration of exogenous oxytocin.

Agalactia: Agalactia is seen occasionally in heifers and can be a primary endocrine problem or a localized problem of the mammary gland. It is occasionally caused by a severe systemic disease or by mastitis caused by *Mycoplasma bovis*. Agalactia has also been associated with cows grazing or eating endophyte-infested fescue.

"Blind" or Nonfunctional Quarters:

Nonfunctional quarters are usually the result of a severe mastitis infection, which may occur in dry or lactating cows or in heifers due to suckling by other heifers or calves. Some of these quarters may occasionally return to production in future lactations. Rarely, blind or nonfunctional quarters may be congenital.

Congenital Disorders: Congenital aberrations include many structural defects, but the most significant disorder is

supernumerary teats. These may be located on the udder behind the posterior teats, between the front and hind teats, or attached to either the front or hind teats. Removal of supernumerary teats from dairy heifers is desirable to improve appearance of the udder, to eliminate the possibility of mastitis in the gland above the extra teats, and to facilitate milking. Most are easily removed surgically when the heifer is from 1 wk to 1 yr old (best done at 3–8 mo of age). Supernumerary teats may be surgically removed from preparturient heifers before lactation begins. The incision should be sutured or stapled after excision of the teat.

TRAUMATIC AND STRUCTURAL DISORDERS

Trauma and Laceration: Superficial wounds to the udder and teats may be cleaned with suitable antiseptic solutions and treated as open wounds with frequent application of antiseptic powders or sprays. If the teats are involved, adhesive tape may hasten healing. Wounds involving the teat orifice should be dressed with antiseptic creams and bandaged after milking. Affected quarters are at very high risk of infection, and prophylactic treatment with intramammary antibiotics is recommended to prevent development of mastitis.

Lacerations of the large milk vein should be considered an emergency because of the potential for severe hemorrhage; prompt compression and ligation of these lacerations is recommended.

Deeper wounds of the udder and teats should be promptly (within 6 hr) cleansed and sutured or stapled under local anesthesia with appropriate sedation and restraint. When the wound involves the teat cistern, it may be necessary to insert a self-retaining teat cannula with removable cap into the teat for the first 24 hr to prevent milk seeping through the wound (which would delay or prevent healing) and to aid in milking. The affected quarter should be infused with antibiotic preparations.

Teat Obstructions: Acquired teat obstructions are usually the result of proliferation of granulation tissue after the occurrence of an observed or unobserved teat injury. Teat obstructions are usually recognized when they interfere with milk flow. They can range from diffuse, tightly adherent lesions to highly mobile discrete lesions that float throughout the gland cistern. Some “floaters” are caused by formation of small masses from butterfat, minerals, and tissue in mammary ducts

during the dry period. These can be recognized by intermittent disruptions in milk flow. They may be removed by forced pressure downward on the teat cistern or by use of specialized instruments inserted through the teat canal. Membranous obstructions in the area of the annular fold at the base of the gland cistern are sometimes seen in heifers. Treatment of these obstructions is generally unsuccessful.

Complete teat obstruction may result when adhesions fill the teat cistern after severe trauma. Treatment is similar to that for stenosis (*see below*), but the prognosis usually is more guarded. In instances of severe injury, milking of the quarter should be permanently discontinued.

Teat stenosis is characterized by a marked narrowing of the teat orifice or streak canal, which makes milking difficult. It usually results from a contusion or wound that produces swelling or formation of a blood clot or scab or from mastitis infections (especially in prelactating heifers). Teat obstructions can be diagnosed initially by careful palpation of the affected gland. Complex teat obstructions or obstructions in valuable animals may require diagnostic imaging such as ultrasonography, contrast radiography, or teloscopy (endoscopy).

Treatment varies depending on severity. Conservative treatment includes the use of teat cannulas and external pressure to remove obstructions, whereas serious cases may require prompt referral to specialists for thelotomy or teloscopy (endoscopic surgery). All injuries to, or surgical procedures on, the teat should be handled carefully to prevent infection. Prophylactic antibiotic infusions of the quarter are indicated when the teat or teat orifice is involved. Permanent fistulas into the teat or gland cisterns are best repaired during the dry period.

Breakdown of Udder Support Apparatus: Rupture of the suspensory ligaments of the udder (usually the medial suspensory ligament) occurs gradually in some older cows and leads to a dropping of the udder floor, resulting in lateral deviation of the teats. Occasionally, acute rupture can occur at or just after parturition. Animals with this condition are at high risk of developing mastitis. There is no successful treatment; supportive trusses generally are not satisfactory. The condition is suspected to have a genetic basis, and these animals are often removed from the milking herd.

Hematomas: Trauma (often related to inadequate housing) can result in contusions

and hematomas of the udder. Hematomas usually appear as soft-tissue swellings located anterior to the foreudder or caudodorsal to the rear udder. They may be difficult to differentiate from abscesses. Severe hematomas can result in anemia if not treated. In most instances, hematomas resolve after conservative treatment consisting of pressure wraps and rest. Hematomas should not be incised or drained unless they become infected. Milking should be performed cautiously during the convalescent period. Hematomas that continue to enlarge should be considered an emergency because of the possibility of excessive blood loss and shock.

Abscesses: Subcutaneous abscesses of the udder (not involving the milk-producing tissue) can develop between the skin and the supporting connective tissue of the udder. Diagnosis is by needle aspiration. Abscesses usually develop secondary to wounds, chronic mastitis, infected hematomas, or severe contusions. They should be incised and drained when chronic and near the surface of the udder. The wound should be flushed daily with an antiseptic solution or water under pressure until healing is complete.

Bloody Milk: The occurrence of pink- or red-tinged milk is common after calving

and can be attributed to rupture of tiny mammary blood vessels. Udder swelling from edema or trauma is a potential underlying cause. Bloody milk is not fit for consumption. In most cases, it resolves without treatment in 4–14 days, provided the gland is milked out regularly. The occurrence of frank blood in a single quarter is likely the result of severe, acute mastitis (see p 1358) or trauma, and milking should be discontinued until hemorrhage is controlled. Intramammary antibiotics should be administered if mastitis is suspected.

Teat Sphincter Inadequacy (“Leakers” or Incontinentia Lactis): High levels of intramammary pressure in high-producing dairy cows may result in milk dripping from teats. Risk factors for milk leakage include high peak milk flow rates, short teats, and inverted teat ends. Shorter intervals or more frequent milking may be recommended when a large proportion of the herd is affected. Occasionally, cows are observed to leak milk continuously. These cows usually have sustained a severe teat injury or have an abnormal streak canal. In general, little can be done to correct this condition, and most of these cows will develop mastitis; it is recommended that persistent leakers be designated for removal from the herd.

UTERINE PROLAPSE AND EVERSION

Prolapse of the uterus may occur in any species; however, it is most common in dairy and beef cows and ewes and less frequent in sows. It is rare in mares, bitches, queens, and rabbits. Invagination of the tip of the uterus, excessive traction to relieve dystocia or retained fetal membranes, uterine atony, hypocalcemia, and lack of exercise have all been incriminated as contributory causes.

Prolapse of the uterus invariably occurs immediately after or within several hours of parturition, when the cervix is open and the uterus lacks tone. Prolapse of the post-gravid uterine horn usually is complete in cows, and the mass of uterus usually hangs below the hocks. The invagination of the contralateral horn, which is prevented from exteriorization by the strong intercornual ligament, can be located by careful examination of the surface of the prolapsed

organ. In sows, one horn may become everted while unborn piglets in the other prevent further prolapse. In small animals, complete prolapse of both uterine horns is usual. A contributory cause in sheep may be grazing estrogenic pastures.

In cows, treatment involves removing the placenta (if still attached), thoroughly cleaning the endometrial surface, and repairing any lacerations. Rubbing the surface of the uterus with glycerol helps reduce edema and provides lubrication. The uterus is then returned to its normal position. An epidural anesthetic should be administered first. If the cow is standing, the cleansed uterus should be elevated to the level of the vulva on a tray or hanmcock supported by assistants, and then replaced by applying steady pressure beginning at the cervical portion (or at the level of the invagination of the nonprolapsed uterine

horn) and gradually working toward the apex. Once the uterus is replaced, a hand should be inserted to the tip of both uterine horns to be sure there is no remaining invagination that could incite abdominal straining and another prolapse. Installation of warm, sterile saline solution is useful to ensure complete replacement of the tip of the uterine horn without trauma. If recumbent, the cow should be positioned with the hindquarters elevated by placing her in sternal recumbency with the hindlegs extended backward. When elevating the hindquarters of the cow, care should be taken to lift the prolapsed uterus with the hindquarters to prevent stretching and laceration of the uterine artery.

Replacement of the prolapsed uterus in mares is done in a similar way, usually with the mare sedated but standing, taking care not to perforate the uterus.

In sows and small animals, the uterus may be repositioned by simultaneously manipulating it from outside with one hand and through an abdominal incision with the other. Resection of the uterus is indicated in longstanding cases in which tissue necrosis has occurred. Once the uterus is in its normal position, oxytocin (up to 5 IU, IV, or up to 20 IU depending on species, IM) is administered to increase uterine tone. Administration IV of calcium-containing solutions is indicated in most cases, also as

a means of increasing uterine tone. Caslick sutures or other forms of vulvar closure are not useful, because the uterine prolapse begins at the apex of the uterine horn. Prevention of recurrence depends on complete and correct replacement of the uterus and restoration of uterine tone.

The prognosis depends on the amount of injury and contamination of the uterus. The prognosis is favorable when a clean, minimally traumatized uterus is promptly replaced. There is no tendency for the condition to recur at subsequent parturitions.

Complications tend to develop when laceration, necrosis, and infection occur, or when treatment is delayed. Shock, hemorrhage, and thromboembolism are potential sequelae of a prolonged prolapse. In some instances, the bladder and intestines may prolapse into the everted uterus. These require careful replacement before the uterus is replaced. The bladder may be drained with a catheter or needle passed through the uterine wall. Elevation of the hindquarters and pressure on the uterus aid in replacement of bladder and intestines. It may be necessary to incise the uterus carefully (in a longitudinal direction) to replace these organs. In cows, amputation of a severely traumatized or necrotic uterus may be the only way to save the animal. Supportive treatment and antibiotic therapy are indicated.

VAGINAL AND CERVICAL PROLAPSE

Eversion and prolapse of the vagina, with or without prolapse of the cervix, occurs most commonly in cattle and sheep. A form of vaginal prolapse, different in pathogenesis, also occurs in dogs (*see* p 1399). In cattle and sheep, the condition is usually seen in mature females in the last trimester of pregnancy. Predisposing factors include increased intra-abdominal pressure associated with increased size of the pregnant uterus, intra-abdominal fat, or rumen distention superimposed upon relaxation and softening of the pelvic girdle and associated soft-tissue structures in the pelvic canal and perineum mediated by increased circulating concentrations of estrogens and relaxin during late pregnancy. Intra-abdominal pressure is increased in recumbent animals. Added to this, sheep tend to face uphill when lying down, so gravity contributes to vaginal eversion and

prolapse. Docking the tails of lambs may damage structures that support the pelvic girdle (eg, coccygeus muscle) and predispose to vaginal prolapse if the tail is docked too short. The tail should be removed at the level of the ventral skin fold, leaving two or three coccygeal vertebrae intact.

The prolapse begins as an intussusception-like folding of the vaginal floor just cranial to the vestibulovaginal junction. Discomfort caused by this eversion, coupled with irritation and swelling of the exposed mucosa, results in straining and more extensive prolapse. Eventually the entire vagina may be prolapsed, with the cervix conspicuous at the most caudal part of the prolapsus. The bladder or loops of intestine may be contained within the prolapsed vagina. As the bladder moves into the prolapsed vagina, the urethra may be occluded. The bladder then fills and

enlarges, which hinders replacement of the prolapsed vagina unless the bladder is first drained. The bladder may even rupture with potentially fatal consequences. Vaginal prolapse may be graded as I (intermittent prolapse, especially when recumbent), II (continuous prolapse), III (continuous prolapse of vagina, bladder, and cervix), or IV (grade II or III with tissue damage by trauma, infection, or necrosis).

Although most common in mature animals in late pregnancy, vaginal prolapse can occur in young, nonpregnant ewes and heifers, especially in fat animals. Predisposing factors include grazing estrogenic plants (especially *Trifolium subterraneum*) or exogenous administration of estrogenic compounds (usually in the form of growth-promotant implants). Cervicovaginal prolapse is more common in stabled than in pastured animals, suggesting that lack of exercise may be a contributing factor. Vaginal prolapse may also be a problem in cows subjected to repeated superovulation for embryo recovery due to repeated exposure to supraphysiologic concentrations of estrogens. A genetic component in the pathogenesis of cervicovaginal prolapse is likely, because a breed predisposition exists in both cattle (Brahman, Brahman crossbreds, Hereford) and sheep (Kerry Hill, Romney Marsh). In pigs, vaginal prolapse is often associated with estrogenic activity of mycotoxins.

For replacement of the prolapsed vagina, an epidural anesthetic is first administered. The organ is washed and rinsed, and the bladder emptied if necessary. Usually, this can be achieved by elevating the prolapsus to allow straightening of the urethra; occasionally, needle puncture through the vaginal wall may be necessary. The vagina is well lubricated (glycerol provides lubrication and reduces congestion and edema by osmotic action) and replaced and then held in position until it feels warm again.

Retention is achieved by insertion of a Buhner suture—a deeply buried, circumferential suture placed around the vestibulum to provide support at the point at which the initial eversion of the vaginal wall occurs.

The Buhner suture has largely superseded earlier attempts to prevent prolapse by various patterns of sutures in the vulvar lips (which do not prevent the initial eversion of the vagina into the vestibulum) or by methods that relied on placement of a retention device within the vagina (which tend to cause discomfort and further straining). Buhner sutures should generally be removed before parturition to prevent extensive laceration. Modification of the Buhner suture to include an exposed, horizontal mattress-like suture has the advantage of remaining in place even when vestibulovaginal tissues have little holding power, and a traditional Buhner suture may be prone to tear through the dorsal or lateral vestibular wall. The Buhner suture and its modifications attempt to replicate the support normally provided by the constrictor vestibuli muscles that are lacking in cases of prolapse. Permanent fixation of the vagina can be achieved by the Johnson button technique, whereby sutures are placed from the vagina, through the sacrospinotuberal ligament and gluteal muscles, and then anchored in the vagina and on the skin with large, flat discs. This can also be accomplished by anchoring the cervix to the prepubic tendon or iliopsoas muscle. Although the cervical os may be edematous and inflamed, cervicovaginal prolapse seldom interrupts pregnancy and does not specifically predispose to dystocia or postpartum uterine prolapse, which has a different etiology.

Vaginal prolapse in sheep may occur simultaneously in many ewes as a herd problem, making surgery impractical. In these cases, use of a commercially available vaginal retention device (a bearing retainer) may be useful. Sheep may lamb without mishap with these devices in place. Permanent fixation techniques (cervicopexy or vaginopexy) have been described in which the cervix or vaginal wall is anchored to other pelvic structures. They may be useful in individual cases of chronic or recurrent prolapse, but most cases are resolved by a well-placed Buhner suture.

VULVITIS AND VAGINITIS IN LARGE ANIMALS

Contusion and hematoma of the vagina are noted infrequently after parturition in all species but particularly in mares and sows. Occasionally, vaginal hematomas in sows may rupture and cause serious (or fatal)

hemorrhage that can be controlled by ligation of the labial branch of the internal pudendal artery. Necrotic vaginitis, vestibulitis, and vulvitis may follow dystocia in all species. Onset of signs, consisting of

arched back, elevated tail, anorexia, dysuria, straining, vulvar and perivulvar swelling, and possibly a fetid, serous discharge, begins within 1–4 days of parturition and may persist for 2–4 wk. In most cases, only gentle and conservative treatment is needed. Prophylactic antibiotic treatment is wise, because clostridial or other organisms may proliferate in the damaged tissue and cause tetanus (*see* p 611), blackleg (*see* p 602), or other forms of clostridial myositis. Possible consequences of necrotic vaginitis include permanent stricture of the vagina, transvaginal adhesions, or perivaginal abscessation.

Vestibular lymphocytic follicles, also called granular venereal disease, granular vulvitis, or granular vulvovaginitis, are seen in cows and are characterized by vestibular hyperemia and hyperplasia of the lymphoid nodules of the vestibular mucosa. These lesions do not constitute a specific disease but reflect irritation of the vestibular mucosa. They can be reproduced experimentally by topical application of *Ureaplasma ureolyticum* or *Mycoplasma* spp in goats and cattle.

Infectious pustular vulvovaginitis of cows is caused by bovine herpesvirus 1 (*see* p 1434) and is transmitted by natural service, nasogenital contact, or mechanically by insects such as flies. It is characterized by vaginal lesions. Affected cows show signs of vaginal discomfort (raised tail, frequent urination) and have numerous, round, white, raised lesions of the vestibular mucosa. Within a short time, these lesions progress to pustules and erosions or ulcers. Mucopurulent discharge may be prominent, even in pregnant animals in which pregnancy is uninterrupted. The histologic lesion consists of necrosis of vestibular and vaginal epithelium, with intranuclear inclusion bodies typical of herpesvirus infection. The virus may be secreted in the semen of infected bulls (which have similar lesions of the penis and prepuce). Intrauterine inoculation of the virus produces necrotizing endometritis and cervicitis.

A severe disease characterized by vaginitis in cows and epididymitis in bulls occurs sporadically in eastern and southern Africa, where it is referred to as epivag. The disease is spread by natural mating. In the early stages of infection, cows have intense vaginitis characterized by reddened mucosae without ulcers, erosions, or vesicular lesions. A thick, creamy, white to

yellow discharge develops. The infection spreads to the uterus and uterine tubes, and salpingitis and fimbrial adhesions frequently result in permanent infertility. Although epivag has been transmitted experimentally by transferring exudate, the cause is unknown.

Necrotic vulvitis has been observed as a severe granulomatous and necrotic lesion centered on the ventral commissure of the vulva of cows, sometimes occurring in outbreak form. It is associated with several pathogens, possibly acting synergistically and, in particular, *Porphyromonas levi*.

Catarrhal bovine vaginitis has been reported from many countries. Although enteroviruses have been associated with this condition, the cause remains unknown. In areas of the world where bovine tuberculosis (*see* p 687) is still endemic, vaginal lesions may be either a primary lesion after service by a bull with genital infection or evidence of uterine disease or of cervicitis.

One cause of vulvitis in sheep is ulcerative dermatosis (*see* p 872), characterized by crusted ulcers of the vulvar skin, penis, prepuce, and facial skin. Posthitis and vulvitis are also caused by the interaction of a high-protein diet and infection with urease producing organisms, usually *Corynebacterium renale*. *Demodex* mites have been seen in the vulvar skin of sheep; they usually are not associated with lesions but may produce granulomas.

Equine coital exanthema (*see* p 1357) is caused by equine herpesvirus 3. It is an acute disease without systemic signs. Red papules appear in the vaginal and vestibular mucosae 2–10 days after infection, which occurs as a result of mating with an infected stallion. Lesions extend to the perivulvar skin. The lesions progress rapidly to pustules, then ulcerate, and finally heal, leaving depigmented scars. Stallions show similar lesions on the penis and prepuce. The disease causes discomfort and may prevent mating but does not specifically inhibit fertility.

Dourine (*see* p 38) is a venereal disease of horses. Early signs are characterized by edematous swelling of the vulva and secondary vulvovaginitis of the swollen, irritable tissue.

Coital injuries of cows and mares may be attributable to the relatively large size of the penis in these species compared with the vagina. Injuries of the vulva and vagina may be caused by horned cattle. Vaginal injuries in a variety of species have also been inflicted maliciously.

REPRODUCTIVE DISEASES OF THE FEMALE SMALL ANIMAL

See *also* MANAGEMENT OF REPRODUCTION: SMALL ANIMALS, p 2219.

Most “infertile” dogs are healthy and fertile. Breeding practices should be reviewed before engaging in diagnostic testing for the less common causes of canine infertility. A basic understanding of the reproductive cycle of the bitch is essential to diagnose “infertility” problems related to breeding at the incorrect time, artificial insemination, etc. Most bitches cycle twice a year, with an interestrus interval of at least 4 mo. Bitches with <4 mo between two cycles usually do not get pregnant. Some large breeds (eg, Great Danes) may cycle every 9–12 mo with normal fertility.

The bitch is a spontaneous ovulator, ie, ovulation occurs without any breeding stimulus. The bitch starts cycling with the influence of hormones released from the hypothalamus and pituitary glands. Gonadotropin-releasing hormone (GnRH), released from the hypothalamus, stimulates the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). FSH has a primary responsibility for growth of follicles on the ovaries, whereas LH causes ovulation of the follicles.

The **estrous cycle in the bitch** is unique and different from that of other domestic animals. It starts with proestrus, which most breeders refer to as the start of the “season,” when spotting or bleeding from the vagina is noticed. During proestrus, the bitch is attractive to males but does not allow breeding. Estrogen produced by ovarian follicles causes changes in the epithelial cells of the vaginal mucosa, which can be examined by vaginal cytology (*see* p 1607). Estrus or time of receptivity follows proestrus, when the bitch accepts the male for breeding. The duration of proestrus and estrus is traditionally considered to be 9 days each, on average, but each phase can range from 2 or 3 to 21 days. During proestrus, the vulvar lips of the bitch are turgid or firm and become soft and “wrinkly” as the bitch nears the time of receptivity. In most bitches, the bloody discharge of proestrus also changes to a straw color as estrus nears, but some may bleed all the way through estrus.

The production of **progesterone** is also unique during the estrous cycle of the bitch. The early rise of progesterone during estrus is from the luteinized follicles of the ovaries

and can be used in breeding management. The bitch ovulates ~2–3 days after the LH peak. After ovulation, the follicles are replaced by corpora lutea (CLs), which produce progesterone. The production of progesterone continues throughout diestrus, the phase of the estrous cycle after estrus, regardless of whether the bitch is pregnant. The duration of diestrus is the same as that of pregnancy, ~62–63 days from the LH peak. Unlike in other domestic species, in the bitch there is no production of prostaglandin $F_{2\alpha}$ from the endometrium to cause luteolysis (CL regression). During diestrus, many bitches go through pseudopregnancy in which they may gain weight and have an enlarged abdomen; other overt signs may be seen, including mammary gland enlargement, as well as prewhelping behavior such as nesting or “adopting” toys and shoes. The pseudopregnancy (or diestrus) is considered a normal occurrence and may not need any treatment.

Ovulation: The ova released during ovulation in the bitch are at the primary oocyte stage, ie, the first polar body has not come out of the ovum and sperm are unable to penetrate the ovum. It takes ~3 days for the ovum to become a secondary oocyte, which can be penetrated by sperm. Sperm can survive as long as 10 days in the bitch's reproductive tract. This can become a diagnostic challenge when a bitch's owner requests a cesarean section 62 days after breeding, because theoretically the gestation period may be only 52 days. A fairly reliable predictor of whelping is hypothermia or a decrease in rectal temperature of 2°–3°F, caused by a progesterone decrease 12–36 hr before. Vaginal cytology can also be used to predict whelping by determination of day 1 of diestrus.

Reproductive Anatomy: Successful vaginal swabbing technique requires knowledge of the unique reproductive anatomy of the bitch. The vagina of the bitch is very long, ~20 cm (9 in.) in a medium-sized bitch. The cervix is located in the abdominal cavity, whereas it is located in the pelvic inlet in other domestic animals (eg, cow, mare). Therefore, the cervix in the bitch cannot be visualized by an endoscope

or speculum; a flexible endoscope with a light source is required. This is important to deposit semen transcervical in the uterus for artificial insemination (AI). The size of the uterus and ovaries vary considerably with the breed.

Vaginal Cytology: A clean, cotton tip swab is commonly used to swab the vagina to obtain a cytology sample. An endoscope cone or vaginal speculum can be used to guide the swab. A right-handed person can hold the bitch's vulva with a gloved left hand, opening the vulvar lips with the thumb and middle finger, while using the index finger behind the vulva to support it. The swab is moistened with warm tap water and inserted almost vertically into the vagina, avoiding the clitoral area, up and over the brim of the pelvis. It may be helpful to forward the swab, especially in small size bitches and bitches without serosanguineous discharge. If the swab feels "stuck" in the vaginal folds, it may be pulled back slightly and redirected before proceeding. Once the swab is inserted to a depth of at least 6–10 cm (2–4 in.), it is rolled a few times in one direction (if rotated back and forth, the cotton may unroll and drop in the vagina) and withdrawn. Inserting the swab as deep as possible to reach the cranial part of the vagina (versus the caudal part) minimizes collection of extraneous debris. Getting in a habit of reaching the cranial vagina is also helpful to take samples for vaginal culture and for AI. The swab is rolled on a clean microscope slide, air-dried, and stained; two slides are recommended. Stains that can be used include Wright-Giemsa, Romanowsky, methylene blue, eosin-nigrosin, Gram stain, etc. The slides with smears are dipped 5–7 times in each jar, rinsed with tap water, air-dried, and examined under the microscope. Viewing under 200× magnification first is helpful to get an overall impression of the types and distribution of cells before examining more closely under 400× magnification.

Vaginal Cytology Interpretation: Various theriogenologists, clinical pathologists, and other practitioners have interpreted vaginal cytology of the bitch a little differently. One method is described here. The vaginal mucosa is responsive primarily to estrogens, and so vaginal cytology is useful only during the estrogenic phase of the cycle. **Parabasal cells** are small, round cells with large and distinct nuclei. The total area of the cytoplasm part of the cell is smaller than the nucleus. These cells (along with RBCs) are present during proestrus. **Superficial intermediate** cells are larger

than the parabasal cells, with small nuclei and irregular/folded borders. Large numbers of these cells are seen during late proestrus to early estrus. **Superficial cells**, also called cornified or anucleated, are the largest of the epithelial cells present during estrus. Under a simple microscope, the nuclei of these cells appear faded or absent. The cells also appear "light in weight," multi-layered, and with folded borders. The appearance of 80%–90% of these cells in the smear is used to indicate that breeding can start. A series of vaginal cytology samples is needed to observe the progressive change in epithelial cells; only one smear is unreliable. Epithelial cells may remain the same for many days in some bitches, whereas they may change within 24 hr in others. In addition, many bitches reach 80%–90% cornification during estrus, but in others cornification never goes above 70%. In these bitches, waiting for 80%–90% cornification will result in loss of breeding during that cycle. Another breeding management tool is the progesterone assay, discussed below. The appearance of neutrophils on the vaginal cytology sample indicates the first day of diestrus, and whelping will occur 57–58 days later. Daily vaginal cytology samples are recommended because in some bitches, the cells change from cornified to superficial intermediate and neutrophils appear within 24 hours.

Progesterone Assay: Progesterone is secreted not only from the CLs but also from the early luteinized follicles of the ovaries. The early rise in progesterone can be used to determine ovulation in the bitch, which occurs ~3 days after the LH peak. The LH peak is very short. LH kits are available, and LH should be checked every day during the expected ovulation time. Progesterone assays are commonly used for canine breeding management. These ELISA-based qualitative test kits are based on a color change that corresponds to a range of progesterone values. Many clinicians prefer to send the blood samples to an endocrinology laboratory for progesterone determination by radioimmunoassay. Progesterone is the same hormone in all species, including people; therefore, blood samples can be analyzed for progesterone in veterinary or human diagnostic laboratories.

The progesterone assay is an excellent tool to determine ovulation time for appropriate breeding. This becomes critical when using chilled transported or frozen-thawed semen for AI. As in vaginal cytology, progesterone concentration is

monitored starting a few days after the start of proestrus, projecting ahead using progesterone concentrations of 2–10 ng/mL, with 2–2.9 ng/mL indicative of ovulation in approximately 2 days, 3–3.9 ng/mL in 1 day, and 4–10 ng/mL indicative of ovulation day.

DYSTOCIA

Dystocia refers to abnormal or difficult birth. Causes include maternal factors (uterine inertia, inadequate size of birth canal) and/or fetal factors (oversized fetus, abnormal orientation as the fetus enters the birth canal). The condition occurs more commonly in certain breeds. In one survey (253 whelpings, 1,671 pups born), a high frequency of dystocia (32% of the individual bitches and 27.7% of all the whelpings) in Boxers was reported, mainly due to uterine inertia but also to fetal malpresentations.

Dystocia should be considered in any of the following situations: 1) animals with a history of previous dystocia or reproductive tract obstruction, 2) parturition that does not occur within 24 hr after a drop in rectal temperature to <100°F (37.7°C), 3) strong abdominal contractions lasting for 1–2 hr without passage of a puppy or kitten, 4) active labor lasting for 1–2 hr without delivery of subsequent puppies or kittens, 5) a resting period during active labor >4–6 hr, 6) a bitch or queen in obvious pain (eg, crying, licking, or biting the vulva), or 7) abnormal vulvar discharge (eg, frank blood, dark green discharge before any neonates are born [indicates placental separation]).

To determine the appropriate therapy, the cause of dystocia (obstructive vs nonobstructive) must be determined and the condition of the animal assessed. A thorough history regarding breeding dates, previous parturitions, pelvic trauma, etc, is desirable. The animal should be examined for signs of systemic illness that, if present, may necessitate immediate cesarean section. The normal vaginal discharge at parturition is a dark green color; abnormal color or character warrants immediate attention. A sterile digital vaginal examination should be performed to evaluate patency of the birth canal and the position and presentation of the fetus(es). Radiography or ultrasonography can determine the presence and number of fetuses, as well as their size, position, and viability.

Medical management may be considered when the condition of the dam and fetuses is stable, when there is proper fetal position and presentation, and when there is no obstruction. Oxytocin (3–20 U in bitches,

2–5 U in queens) given IM up to 3 times at 30-min intervals, with or without 10% calcium gluconate (3–5 mL, IV slowly) may promote uterine contractions. If no response follows, a cesarean section should be performed.

Surgery is indicated for obstructive dystocia, dystocia accompanied by shock or systemic illness, primary uterine inertia, prolonged active labor, or if medical management has failed.

FALSE PREGNANCY

(Pseudopregnancy, Pseudocyesis)

False pregnancy is common in bitches and uncommon in queens. It occurs at the end of diestrus and is characterized by hyperplasia of the mammary glands, lactation, and behavioral changes. Some bitches behave as if parturition has occurred, “mothering” by nesting inanimate objects and refusing to eat. The possibility of a true pregnancy should be eliminated by the history, abdominal palpation, and abdominal radiographs and ultrasonography.

The falling progesterone and increasing prolactin concentrations associated with late diestrus are believed to be responsible for the clinical signs. No treatment is recommended, because the condition resolves spontaneously in 1–3 wk. In bitches with discomfort secondary to mammary gland enlargement, alternating cold and warm compresses on the engorged mammae or wrapping the abdomen with an elastic bandage may give relief. Owners should be advised not to milk out the mammary glands, because doing so will only stimulate lactogenesis.

Tranquilizers (eg, diazepam, PO, up to 4 days) may be considered for bitches with significant behavioral changes. Estrogens should not be used because of the potential for bone marrow suppression. Megestrol acetate, a progestin (2.5 mg/kg/day, PO, for 8 days), is the only drug currently approved for treatment of false pregnancy in bitches in the USA. Prolonged or repeated use of megestrol acetate may cause pyometra. Androgens (eg, mibolerone, 16 mcg/kg/day, PO, for 5 days) may decrease clinical signs of false pregnancy in bitches. Mibolerone is not approved for treatment of false pregnancy in bitches in the USA. If owners are distressed by repeated bouts of pseudopregnancy, the bitch should either be bred or undergo ovariectomy.

FOLLICULAR CYSTS

These fluid-filled structures develop within the ovary and result in prolonged secretion

of estrogen, continued signs of proestrus or estrus, and attractiveness to males. Ovulation may not occur during this abnormal estrous cycle. Follicular cysts should be suspected in any bitch showing clinical manifestations of estrus for >21 days, or when proestrus plus estrus have lasted for >40 days. Estrous cycles due to follicular cysts in queens may be difficult to differentiate from normal, frequent cycles.

The primary differential diagnosis is functional ovarian granulosa cell tumor. Assessment of vaginal cytology with presence of cornified cells indicates increased serum estrogens.

The treatment of choice is ovariectomy. If the animal is to be bred, induction of luteinization of the cystic follicles may be accomplished by using GnRH (25 mcg, IM) or human chorionic gonadotropin (220 IU/kg, IV, or 1,000 IU, half IV, half IM).

MAMMARY HYPERTROPHY IN CATS

(Fibroadenoma complex, Mammary fibroadenomatosis, Glandular mammary hypertrophy)

This benign condition is characterized by rapid abnormal growth of one or more mammary glands. There are two basic types of hyperplasia of the feline mammary gland—lobular hyperplasia and fibroepithelial hyperplasia. Lobular hyperplasia is seen as palpable masses in one or more mammary glands in intact cats 1–14 yr old. Fibroepithelial hyperplasia occurs in young, cycling, or pregnant cats; in old, intact females and males; and in neutered males after treatment with progestins.

Feline mammary hypertrophy is considered to be a hormone-dependent dysplastic change in the mammary gland. Hyperplasia occurs within 1–2 wk after estrus or 2–6 wk after progestin treatment. The tremendously enlarged glands may appear erythematous, and some of the skin may be necrotic. Edema of the skin and both hindlegs is common, and the condition can easily be confused with acute mastitis.

Ovariectomy or mastectomy is curative, although spontaneous remissions occur. Ovariectomy is followed by regression of the glands and prevents recurrence.

MASTITIS

Mastitis is inflammation of the mammary gland(s) associated with bacterial infection. It occurs in postpartum bitches and less

commonly in postpartum queens. Rarely, mastitis is seen in lactating pseudopregnant bitches. Risk factors for developing mastitis include poor sanitary conditions, trauma inflicted by offspring, and systemic infection. Mastitis may be acute or chronic.

Mastitis may be localized (eg, involving a single gland sinus), diffuse in a single gland, or diffuse within multiple glands. The animal may be asymptomatic or critically compromised. Milk from mastitic glands may appear normal grossly or may be abnormal in color or consistency. In acute mastitis, the affected glands are hot and painful. If acute mastitis progresses to septic mastitis, signs of systemic illness such as fever, depression, anorexia, and lethargy may be seen, and the dam may neglect the neonates. In chronic or subclinical mastitis, the main complaint may be failure of offspring to thrive.

Diagnosis is usually evident from the history and physical examination. Microscopic examination of milk may reveal inflammatory cells. Milk from each gland should be evaluated in any postpartum bitch or queen with signs of systemic illness. Before beginning therapy, a milk sample should be collected (or obtained by fine-needle aspiration) for bacterial culture and sensitivity. Culture of milk or fluid expressed from the affected glands yields moderate to heavy growth of *Escherichia coli* or staphylococci.

Broad-spectrum, bactericidal antibiotics should be chosen based on sensitivity tests and with the understanding they will be passed in the milk to the young. Antibiotics such as tetracycline, chloramphenicol, or aminoglycosides should be avoided during lactation unless the neonates are weaned. Cephalexin (5–15 mg/kg, PO, tid) and amoxicillin/clavulanate (14 mg/kg, PO, bid-tid) are recommended as initial therapeutic agents pending culture results. Hot-packing the affected gland encourages drainage and seems to relieve discomfort. Fluid therapy is indicated in animals with septic mastitis that are dehydrated or in shock. An abscessed mammary gland should be lanced, drained, flushed, and treated as an open wound.

Nonseptic mastitis is seen most commonly at weaning. The affected glands are warm, swollen, and painful to the touch, but the animal is alert and healthy. Warm compresses should be applied to the affected glands 4–6 times daily, and the young should be encouraged to nurse from these glands. When galactostasis occurs at weaning, lactation can be diminished by reducing food and water intake of the dam.

The mammary glands should not be stimulated during this time. Appropriate food and water must be provided for the young.

METRITIS

Metritis is postpartum infection of the uterus. Predisposing causes include prolonged delivery, dystocia, and retained fetuses or placentas. *Escherichia coli* is the most common bacterium isolated from the infected uterus; streptococci, staphylococci, *Proteus* sp, and others are isolated less frequently.

The primary clinical sign is purulent vulvar discharge. Bitches or queens with metritis are usually depressed, with signs of fever, lethargy, and inappetence, and may neglect their offspring. Pups may become restless and cry incessantly. Metritis should be considered in any postpartum animal with signs of systemic illness or an abnormal vaginal discharge. A large, flaccid uterus may be palpable. Radiographs should be taken to determine whether fetuses or placentas are retained. The hemogram may show leukocytosis with a left shift.

Treatment includes stabilization with IV fluids, supportive care, and antibiotic therapy based on culture and sensitivity testing of the vulvar discharge. Prostaglandin $F_{2\alpha}$ (0.1–0.25 mg/kg, SC, for 2–3 days) or oxytocin (5–20 U in bitches, 2–5 U in queens, IM) may help evacuate the uterine contents. Ovariohysterectomy is recommended after initial stabilization if the animal is extremely ill or if future reproduction is unimportant. Otherwise, it should be considered an elective procedure to be performed when lactation has ceased.

OVARIAN REMNANT SYNDROME

Ovarian remnant syndrome refers to clinical signs indicating the presence of functional ovarian tissue in a previously ovariohysterectomized bitch or queen. It is not a pathologic condition but a complication of ovariohysterectomy. It occurs when a retained piece of ovarian tissue revascularizes and becomes functional. The most common presentation is recurrent estrus (eg, vulvar swelling, flagging, standing to be mounted) after ovariohysterectomy.

Differential diagnoses include vaginitis, uterine stump pyometra, and exogenous estrogen therapy. Presumptive diagnosis of ovarian remnant syndrome requires demonstration of a cornified vaginal epithelium in a spayed female. A commercially available luteinizing hormone test can

be used to distinguish ovariectomized and sexually intact bitches.

Exploratory laparotomy to find and remove the ovarian remnant is the treatment of choice.

PYOMETRA

Pyometra is a hormonally mediated diestral disorder characterized by cystic endometrial hyperplasia with secondary bacterial infection. Pyometra is reported primarily in older bitches (>5 yr old), 4–6 wk after estrus.

Etiology: Factors associated with occurrence of pyometra include administration of longlasting progestational compounds to delay or suppress estrus, administration of estrogens to mismated bitches, and postinsemination or postcopulation infections. Progesterone promotes endometrial growth and glandular secretion while decreasing myometrial activity. Cystic endometrial hyperplasia and accumulation of uterine secretions ultimately develop and provide an excellent environment for bacterial growth. Progesterone may also inhibit the WBC response to bacterial infection. Bacteria from the normal vaginal flora or subclinical urinary tract infections are the most likely sources of uterine contamination. *Escherichia coli* is the most common bacterium isolated in cases of pyometra, although *Staphylococcus*, *Streptococcus*, *Pseudomonas*, *Proteus* spp, and other bacteria also have been recovered.

Because queens require copulatory stimulation to ovulate and produce progesterone from corpora lutea, pyometra is less common in queens than in bitches. Administration of medroxyprogesterone and other progestational compounds has been associated with development of pyometra in bitches and queens. Pyometra can develop in uterine tissue left after ovariohysterectomy (stump pyometra). It can also occur secondary to postpartum metritis.

By itself, estrogen does not contribute to the development of cystic endometrial hyperplasia or pyometra. However, it does increase the stimulatory effects of progesterone on the uterus. Administration of exogenous estrogens to prevent pregnancy (ie, “mismatch shots”) during diestrus greatly increases the risk of developing pyometra and should be discouraged.

Clinical Findings: Clinical signs are seen during diestrus (usually 4–8 wk after estrus) or after administration of exogenous

progestins. The signs are variable and include lethargy, anorexia, polyuria, polydipsia, and vomiting. When the cervix is open, a purulent vulvar discharge, often containing blood, is present. When the cervix is closed, there is no discharge and the large uterus may cause abdominal distention. Signs can progress rapidly to shock and death.

Physical examination reveals lethargy, dehydration, uterine enlargement, and if the cervix is patent, a sanguineous to mucopurulent vaginal discharge. Only 20% of affected animals have a fever. Shock may be present.

The leukogram of animals with pyometra is variable and may be normal; however, leukocytosis characterized by a neutrophilia with a left shift is usual. Leukopenia may be found in animals with sepsis. A mild, normocytic, normochromic, nonregenerative anemia (PCV of 28%–35%) may also develop. Hyperproteinemia due to hyperglobulinemia may be found. Results of urinalysis are variable. With *E coli* uterine infection, isosthenuria due to endotoxin-induced impairment of renal tubular function or to insensitivity to antidiuretic hormone (or both) may develop. A glomerulonephropathy caused by immune-complex deposition may result in proteinuria. These renal lesions are potentially reversible once the pyometra is resolved.

Diagnosis: Pyometra should be suspected in any ill, diestral bitch or queen, especially if polydipsia, polyuria, or vomiting is present. The diagnosis can be established from the history, physical examination, abdominal radiography, and ultrasonography. Vaginal cytology often helps determine the nature of the vulvar discharge. A CBC, biochemical profile, and urinalysis help

exclude other causes of polydipsia, polyuria, and vomiting; they also evaluate renal function, acid-base status, and septicemia. The uterine exudate should be cultured and sensitivity tests performed. Differential diagnoses include pregnancy and other causes of vulvar discharge, polyuria and polydipsia, and vomiting.

Treatment and Prognosis: Ovariohysterectomy is the treatment of choice for pyometra. Medical management could be considered if preserving the reproductive potential of the bitch or queen is desired. Fluids (IV) and broad-spectrum, bactericidal antibiotics should be administered. Fluid, electrolyte, and acid-base imbalances should be corrected as quickly as possible, before ovariohysterectomy is performed. The bacterial infection is responsible for the illness and will not resolve until the uterine exudate is removed. Oral antibiotics (based on the results of the culture and sensitivity) should be continued for 7–10 days after surgery.

Medical therapy with prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) can be used for animals to be bred in the future, although prostaglandins are not approved in the USA for use in cats or dogs. $PGF_{2\alpha}$ causes luteolysis, contraction of the myometrium, relaxation of the cervix, and expulsion of the uterine exudate. They should probably not be used in animals >8 yr old or in those not intended for breeding. The delay before clinical improvement and the many adverse effects of $PGF_{2\alpha}$ preclude its use in a severely ill animal. $PGF_{2\alpha}$ also should be used with caution in bitches or queens with a closed-cervix pyometra because of increased risk of uterine rupture. Pregnancy must be excluded, because prostaglandins can induce abortion.

Naturally occurring $PGF_{2\alpha}$ (0.25 mg/kg/day, SC, for 5 days) is commonly used. Synthetic analogues (eg, cloprostenol, fluprostenol, and prostalene) are much more potent than natural $PGF_{2\alpha}$ and have been used to treat pyometra in dogs. Broad-spectrum, bactericidal antibiotics, chosen on the basis of culture and sensitivity tests, should be given for ≥ 2 wk.

The adverse effects of $PGF_{2\alpha}$ include restlessness, anxiety, panting, hypersalivation, pacing, tachycardia, vomiting, urination, and defecation. In cats, vocalization and intense grooming behavior also may be seen. These reactions disappear within 2 hr of the injection. The LD_{50} of $PGF_{2\alpha}$ in dogs is 5.13 mg/kg. Severe ataxia, respiratory distress, and muscle tremors may be seen in queens given 5 mg/kg. If adverse effects are severe, IV fluids at rates appropriate for treatment of shock are

Pyometra in a 10-yr-old Norwegian Elkhound, lateral projection. Courtesy of Dr. Ronald Green.

indicated. Uterine evacuation after an injection is variable.

Other antiprogesterins (eg, aglepristone) are available in some European countries. Clinicians using aglepristone report virtually no adverse effects as compared with prostaglandins. Aglepristone is also used to treat bitches with closed-cervix pyometra. In one study, a dosage of 10 mg/kg given on days 1, 2, and 8 in 15 bitches with closed pyometra led to opening of the cervix after 26 ± 13 hr in all treated animals.

Animals should be reexamined 2 wk after completion of medical therapy. If a sanguineous or mucopurulent vulvar discharge or uterine enlargement is still present, $\text{PGF}_{2\alpha}$ therapy, using the same protocol, may be repeated; however, the prognosis for recovery is much worse. After medical therapy, the prognosis for initial resolution of the pyometra is good if the cervix is open but guarded to poor if closed. Of those animals that respond, as many as 90% of bitches and 70% of queens with open-cervix pyometra may be fertile. Recurrence is likely; 70% of bitches treated medically for pyometra had recurrence within 2 yr. Therefore, the animal should be bred on the next and each subsequent cycle until the desired number of puppies or kittens has been produced, and then spayed. Prostaglandins should not be dispensed for owner administration because of the narrow safety index and the potential to trigger asthmatic events and pregnancy loss in people.

SUBINVOLUTION OF PLACENTAL SITES

Subinvolution of placental sites (SIPS) is abnormal repair of the endometrial placental sites. This disorder is most common in young bitches (<3 yr old) after whelping a first litter. Bitches with SIPS are normal except for hemorrhagic uterine discharge passing from the vulva for several weeks postpartum. Diagnosis is by exclusion; differentials include metritis, vaginitis, and cystitis. Treatment is supportive. Ovariohysterectomy is recommended for bitches that become anemic enough to require transfusion and for bitches not intended for future breeding.

VAGINAL HYPERPLASIA

(Vaginal prolapse)

In vaginal hyperplasia, a proliferation of the vaginal mucosa, usually originating from the floor of the vagina anterior to the urethral orifice, occurs during proestrus and estrus

as a result of estrogenic stimulation. Occasionally, the prolapse continues throughout pregnancy or recurs at parturition. The most common sign is a mass protruding from the vulva. Initially, the surface is smooth and glistening, but with prolonged exposure it becomes dry and fissures develop. A slight vaginal discharge may be present. Although the hyperplastic tissue originates near the urethral orifice, dysuria is uncommon. Vaginal hyperplasia interferes with copulation. Reluctance to breed or failure of intromission may be the only clinical sign if the hyperplastic tissue is contained within the vaginal vault. Vaginal hyperplasia resolves spontaneously as soon as estrogen declines.

The diagnosis is made by the history (stage of the estrous cycle) and examination of the vagina. Estrogenic stimulation could be confirmed by cornification of the vaginal epithelial cells, the presence of the characteristic serosanguineous estrous discharge, and the presence of estrous behavior. The differential diagnosis is vaginal neoplasia, which can be excluded by biopsy of the protruding tissue.

If the hyperplastic tissue is not causing problems, therapy is not indicated. However, if it protrudes from the vulva, it should be kept clean and moist and an antibiotic ointment applied. An Elizabethan collar may be necessary to prevent self-trauma. These animals may be bred by artificial insemination. The hyperplasia regresses as soon as the follicular phase of the estrous cycle has passed. Submucosal resection may be necessary if the mass is extremely large or if mucosal damage is extensive. Recurrence is common even after surgical resection. Vaginal hyperplasia resolves within days of removal of estrogen. Rarely, the hyperplasia recurs at parturition, presumably associated with a burst of estrogen. Ovariohysterectomy, the treatment of choice, permanently corrects this condition by removing the gonadal source of estrogen, thus preventing recurrence.

VAGINITIS

Inflammation of the vagina may occur in prepubertal or mature (intact or spayed) bitches. It is rare in queens. Vaginitis usually is due to bacterial infection, which may be secondary to conformational abnormalities such as vestibulovaginal strictures. Viral infection (eg, herpes), vaginal foreign bodies, neoplasia, hyperplasia of the vagina, androgenic steroids (eg, mibolerone), or intersex conditions also may cause vaginitis.

The most common clinical sign is a vulvar discharge. Licking of the vulva, attraction of males, and frequent micturition also may be seen. Signs of systemic illness are not present, and the hemogram and biochemical profile are normal. The absence of these abnormalities helps differentiate vaginitis from open-cervix pyometra, the most important differential diagnosis. The diagnostic evaluation should include a digital examination of the vagina, vaginoscopy, cytology, and if necessary, culture of the exudate, as well as abdominal radiographs or ultrasonography to evaluate the uterus. An anterior vaginal culture may be obtained using a guarded sterile culture swab. The vagina contains normal bacterial flora;

therefore, culture results must be interpreted cautiously. A heavy growth, especially of one organism, is probably more significant than a light growth of several organisms.

Predisposing factors such as foreign material or anatomic abnormalities should be corrected. Bacterial infection may respond to local treatment (ie, vaginal douches). Systemic, broad-spectrum, bactericidal antibiotics may be needed for persistent infections. Prepubertal animals often do not require treatment, because the vaginitis nearly always resolves with the first estrus. Therefore, it may be wise to delay elective ovariectomy in affected animals until after their first estrous cycle.

REPRODUCTIVE DISEASES OF THE MALE SMALL ANIMAL

See also MANAGEMENT OF REPRODUCTION: SMALL ANIMALS, p 2219, and PROSTATIC DISEASES, p 1405.

ORCHITIS AND EPIDIDYMITIS

Acute inflammation of the testis or epididymis can be caused by trauma, infection (fungal, bacterial, or viral), or testicular torsion. Infection can be hematogenous or urologic in origin. Clinical signs are pain and swelling of the testes, epididymides, and/or scrotum. There may be wounds or other lesions in the scrotal skin. Orchitis and epididymitis are rare in cats unless due to trauma.

The scrotal contents should be carefully palpated to identify which structures are involved, including the epididymis and testis, but patient discomfort and edema can make palpation difficult. Ultrasonography (with sedation or analgesia as needed) is helpful to further evaluate the affected structures and to confirm the presence of testicular torsion and focal (eg, mass, abscess) lesions in the testis or epididymis. It can also identify less common causes of scrotal enlargement such as scrotal hernia or hematoma.

Diagnostic tests should always include evaluation for *Brucella canis* infection. (See also BRUCELLOSIS IN DOGS, p 1402.) Cytologic examination of semen with bacterial and mycoplasmal culture are also helpful, but semen collection from animals that are ill or in pain may be difficult. Testicular or epididymal specimens for cytology and

culture may be obtained by fine-needle aspiration. Testicular biopsy for histopathology and bacterial culture may be performed, if needed, after less invasive diagnostic tests have been completed. Because of the greater risk of granuloma formation, epididymal aspiration and biopsy are rarely done. If future reproduction is not of importance, specimens can easily be obtained during castration.

Treatment is difficult unless the underlying cause can be identified. The prognosis for maintaining fertility is guarded despite aggressive therapy because of the potential for irreversible damage to the germinal epithelium, tubular degeneration, development of immune-mediated orchitis, or obstruction of the duct system. These sequelae may take months to occur. Application of cool water packs may decrease testicular damage caused by local swelling and hyperthermia; care must be taken not to damage the scrotal skin. In the case of unilateral involvement, the unaffected testis/epididymis must be protected from damage by heat, pressure, and direct extension of the disease process. Hemicastration may be prudent. If bacterial cultures are positive, appropriate systemic antibiotics should be administered for 3–4 wk. There is no completely successful treatment for *B. canis* infection. All antifungal agents interfere with spermatogenesis, either directly or indirectly. The potential for involvement of the prostate by direct extension dictates the use of

antibiotics with good prostatic penetration once inflammation has subsided (fluoroquinolones). Culture and sensitivities should refine therapy.

Histopathology may suggest an immune-mediated process (eg, lymphocytic-plasmacytic infiltration); treatment with immunosuppressive drugs has been attempted without success. Chronic *B canis* infection also causes lymphocytic-plasmacytic inflammation. Furthermore, as a result of inhibitory effects on the hypothalamic-pituitary-gonadal axis, glucocorticoids can cause testicular atrophy and infertility. The ischemic damage caused by testicular torsion becomes irreversible within hours. When maintaining fertility is not important, castration is the treatment of choice for orchitis and epididymitis due to any cause. Lesions of the scrotal skin are treated the same as other skin lesions, keeping in mind that resection of scrotal skin can promote thermal damage to the testes.

Chronic orchiepididymitis may develop as a sequela of the acute syndrome, or there may be no previous history of testicular inflammation. Possible causes include those of acute orchiepididymitis, immune-mediated orchitis and epididymitis, neoplasia, and spermatocoele or granuloma formation. Most animals are asymptomatic except for infertility. Physical examination often reveals testicular atrophy. Tumors may be palpable. Palpation of the epididymis may reveal induration or enlargement, which may erroneously be interpreted as dramatic relative to the atrophic testis. Epididymal atrophy is uncommon. Ultrasonography can help identify the lesions.

Other noninflammatory causes of testicular atrophy include previous exposure to excessive pressure, heat, cold, and cytotoxic agents. Hormonal causes (eg, glucocorticoids, estrogen from contralateral Sertoli cell tumor, iatrogenic exposure to human transdermal hormone replacement therapy) are also possible.

The prognosis for return of normal fertility in cases of chronic orchitis/epididymitis is grave. If warranted by the dog's value as a stud, the diagnostic and therapeutic plan is as described above for the acute condition.

BALANOPOSTHITIS

Inflammation of the penile or preputial mucosa is common in dogs. The normal preputial secretions usually do not result in overt clinical signs. Mild balanoposthitis, resulting in a slight mucopurulent preputial discharge, is present in many sexually

mature dogs, resolves spontaneously, and is of little clinical significance. Diagnostic tests and treatment are not necessary, except as needed for reasonable hygiene. Trauma, lacerations, neoplasia, foreign bodies, urinary tract infection, urolithiasis, or phimosis may result in development of more severe balanoposthitis. A mucopurulent preputial discharge is the most common clinical sign. Excessive licking of the prepuce may also be noted. Swelling of the prepuce and pain are rarely present except in cases of trauma, snake bite, or foreign bodies. If signs of systemic illness are present, the possibility of a more serious concomitant disorder should be considered. Balanoposthitis is rare in cats.

The penis and prepuce should be thoroughly examined, to the level of the fornix, for underlying predisposing factors. The use of saline infusion through a rigid endoscope facilitates this examination, but an otoscope can be used if necessary. Sedation or general anesthesia may be needed. Preputial cytology may be helpful. Bacterial cultures of the preputial cavity, although sometimes difficult to interpret because of the presence of normal preputial flora, may help identify unusual organisms and determine antibiotic sensitivities for refractory cases. Foreign bodies can be submucosal and difficult to see, so tiny tracts should be explored.

Treatment includes correcting any predisposing factors, clipping long hair away from the preputial orifice, and thoroughly flushing the preputial cavity with a mild antiseptic (eg, dilute povidone-iodine or chlorhexidine) or sterile saline solution. If bacterial infection is suspected, an antibiotic ointment may be infused into the preputial cavity for 7–10 days. Recurrence of mild balanoposthitis is common irrespective of therapy. Castration may diminish genital secretions but will not abolish them.

PARAPHIMOSIS

The inability to completely retract the penis into the preputial cavity usually occurs after erection. It is seen most often after semen collection or coitus. The skin at the preputial orifice becomes inverted, trapping the extruded penis and impairing venous drainage. Other causes of paraphimosis include a small preputial opening, priapism, foreign objects around the penis, a constricting band of hair at the preputial orifice, or trauma. Paraphimosis is easily differentiated from priapism (persistent erection without sexual stimulation), congenitally shortened prepuce, congenital

deformity of the os penis, or penile neoplasia or hematoma on the basis of physical examination and palpation.

Paraphimosis warrants veterinary intervention if not resolved quickly. The exposed penis quickly becomes edematous, because its venous drainage is compromised. With continued exposure, the mucosa becomes dry and painful. Self-trauma exacerbates the condition. If recognized early, before severe edema and pain develop, paraphimosis is easily treated. Treatment begins with gentle cleansing and liberal lubrication of the exposed penis. The penis is then replaced inside the prepuce by first sliding the prepuce in a posterior direction, extruding the penis further. This everts the skin at the preputial orifice; usually the prepuce then slides easily over the penis. The edema resolves promptly once circulation is restored. Hypertonic solutions can be useful in difficult cases. If the everted prepuce does not slide over the edematous, exposed penis, a cold compress may be applied with gentle digital pressure to act as a pressure bandage. A temporary purse string suture can be placed to keep the penis inside the prepuce.

With paraphimosis due to other causes, or of longer duration, sedation or general anesthesia can be required. It may be necessary to incise the preputial skin to thoroughly examine the preputial cavity, remove restricting material, and relieve venous obstruction. The penis is then replaced in the preputial cavity, and the incision is closed. If the urethra has been damaged, temporary placement of a closed-system indwelling urinary catheter may be needed to prevent stricture formation.

PRIAPISM

Priapism is a persistent erection without sexual stimulation and is diagnosed by physical examination. Partial paraphimosis can also result. Priapism can be caused by myelopathy, drugs, vascular abnormalities, penile masses, or trauma, or it can be idiopathic. It can be ischemic and a medical emergency. If nonischemic and no primary cause is identified, therapy with gabapentin, ephedrine, or terbutaline can be attempted. Castration is not helpful, because priapism is not testosterone mediated.

If necrosis or gangrene is severe, amputation of the penis and prepuce and urethrostomy might be necessary.

PHIMOSIS

An abnormally small preputial orifice, resulting in inability to extrude the penis, can be congenital, or acquired as a result of neoplasia, edema, or fibrosis after trauma, inflammation, or infection. Clinical signs are variable. Usually, the problem is unnoticed until the dog attempts to mate and is unable to copulate. Urine can pool in the prepuce and cause posthitis. Diagnosis is established by physical examination of the prepuce and penis. Treatment depends on severity of the stenosis and intended use of the dog. If the dog is not used for breeding, therapy probably is not needed, although castration should be considered to prevent arousal. Surgical enlargement of the preputial orifice is indicated if the animal is to be used for breeding, if the phimosis contributes to balanoposthitis, or in the unlikely event that phimosis interferes with normal micturition.

BRUCELLOSIS IN DOGS

Although dogs occasionally become infected with *Brucella abortus*, *B suis*, or *B melitensis*, these sporadic occurrences typically are closely associated with exposure to infected domestic livestock (see p 1348).

B canis is a cause of abortion at 45–55 days of gestation in kenneled dogs. Dogs are the only definitive host of this organism. Infection has caused a reduction of 75% in the number of pups weaned in some breeding kennels. The disease disseminates rapidly among closely

confined dogs, especially at time of breeding or when abortions occur. Transmission occurs via ingestion of contaminated materials or venereal routes. Urine transmission has been reported but seems to be unusual. Both sexes appear to be equally susceptible.

Primary signs are abortion during the last trimester of pregnancy without premonitory signs, stillbirths, and conception failures. Prolonged vaginal discharge usually follows abortion. Abortions may occur during subsequent pregnancies. Infected dogs may

develop generalized lymphadenitis and frequently epididymitis, periorchitis, and prostatitis. Spondylitis and uveitis are occasional complications. Bacteremia is frequent and persists for ~18 mo after exposure. Fever is not characteristic.

Diagnosis is based on isolation and identification of the causative agent or by serology. The organisms can usually be readily isolated from vaginal exudate, aborted pups, blood, milk, or semen of infected dogs. The most widely used serologic test is an agglutination test by a tube or slide method. Nonspecific agglutination reactions occur in some dogs. To eliminate nonspecific antibody reactions, the serum is treated with 2-mercaptoethanol and retested. An agar gel immunodiffusion test performed in some laboratories is quite specific. Other tests, such as immunofluorescence and ELISA, have been used sometimes.

Attempts at immunization have not been successful. Control is based on elimination

or isolation of infected dogs identified by positive cultural or serologic tests at monthly intervals. Incidence of infection is much lower in kennels where dogs are caged individually. Longterm therapy, eg, with a combination regimen of streptomycin or gentamicin and tetracycline, has been successful in many cases. Neutering of infected dogs is sometimes an alternative to euthanasia.

Prevention of canine brucellosis is done by testing before entry and breeding. The disease is reportable in some states. *B canis* is zoonotic, although cases of human infection are rare and less severe than those caused by the smooth species of the genus. The true incidence is unknown. Diagnostic tests used for smooth species do not cross-react with those for rough species; this may result in a missed diagnosis. In addition, signs of *B canis* infections may resemble those of other diseases. Appropriate measures to prevent exposure should be taken.

MAMMARY TUMORS

The frequency of mammary neoplasia in different species varies tremendously. The dog is by far the most frequently affected domestic species, with a prevalence ~3 times that in women; ~50% of all tumors in the bitch are mammary tumors. Mammary tumors are rare in cows, mares, goats, ewes, and sows. There are differences in both biologic behavior and histology of mammary tumors in dogs and cats. Approximately 45% of mammary tumors are malignant in dogs, whereas ~90% are malignant in cats, and dogs have a much higher number of complex and mixed tumors than do cats.

Etiology: The cause of mammary tumors is unknown in any species except mice, in which an oncornavirus is causative in certain inbred strains. Hormones play an important role in the hyperplasia and neoplasia of mammary tissue, but the exact mechanism is unknown. Estrogen or progesterone receptors (or both) have been reported on mammary tumor cells in animals; these may influence the pathogenesis of hormone-induced mammary neoplasia as well as the response to hormone therapy.

Genetic and nutritional effects on mammary neoplasia have been identified in mice and some people but are still not as well understood in dogs or cats. In people, BRCA1 and BRCA2 are the most important genes significantly associated with mammary tumors. In dogs, one single nucleotide polymorphism (SNP) in exon 9 of BRCA1 and one SNP in exon 24 of BRCA2 were found to be significantly associated with canine mammary tumors. It has been demonstrated that the consumption of red meat, obesity at 1 yr of age, and obesity a year prior to diagnosis are associated with an increased risk of mammary gland tumors in intact or ovari hysterectomized dogs. Obesity is thought to mediate breast cancer risk in postmenopausal women by increasing circulating free estrogen levels as well as through increased local estrogen production by aromatases. It is possible that obesity increases risk of mammary tumors through similar mechanisms in dogs.

From a practical view, all mammary tumors should be regarded as potentially malignant regardless of the size or number of glands involved. Spread of mammary carcinomas in both dogs and cats is primarily to regional lymph nodes and

lungs. In dogs, 5%–10% of mammary carcinomas may produce skeletal metastases, primarily in the axial skeleton, but also in long bones.

Canine Mammary Tumors: Mammary tumors in dogs are most frequent in intact bitches; they are extremely rare in male dogs. Ovariectomy before the first estrus reduces the risk of mammary neoplasia to 0.5% of the risk in intact bitches; ovariectomy after one estrus reduces the risk to 8% of that in intact bitches. Bitches neutered after maturity have generally been considered to have the same risk as intact bitches. However, questions remain regarding the impact of ovariectomy at the time of tumor excision. Questions also remain about the timing of such surgery relative to survival. In one study, dogs spayed <2 yr before tumor excision lived 45% longer than either intact dogs or those spayed >2 yr before tumor excision.

The two posterior mammary glands are involved more often than the three anterior glands. Grossly, tumors appear as single or multiple nodules (1–25 cm) in one or more glands. The cut surface is usually lobulated, gray-tan, and firm, often with fluid-filled cysts. Mixed mammary tumors may contain grossly recognizable bone or cartilage on the cut surface.

More than 50% of canine mammary tumors are benign mixed tumors; a smaller percentage of malignant mixed tumors are seen. In the latter, epithelial or mesenchymal components, either singly or in combination, may produce metastases. Histologically, canine mammary gland tumors have been classified by the World Health Organization as carcinomas (with six types and additional subtypes), sarcomas (four types), carcinosarcomas (mixed mammary tumors), or benign adenomas. This classification scheme is based on the extent of the tumor, involvement of lymph nodes, and presence of metastatic lesions (TNM system); it includes unclassified tumors and apparently benign dysplasias. In addition to tumor size and the status and timing of neutering, special stains (including those for the KIT receptor and AgNOR) may have prognostic value.

Feline Mammary Tumors: Mammary tumors in cats are most common in older (average 11 yr) intact females. Cats spayed before 6 mo or 12 mo of age have a 91% or an 86% reduction, respectively, in the risk of mammary carcinoma development than intact cats. Parity does not affect feline mammary carcinoma development. Unlike in dogs, in cats the two anterior or thoracic

glands are more frequently involved than the posterior glands.

Histologically, most feline mammary tumors are adenocarcinomas, with tubular or papillary types more common than solid or mucoid types. Mixed mammary tumors and sarcomas are less commonly diagnosed than carcinomas. Benign tumors of the feline mammary gland are relatively infrequent and account for only ~10% of these tumors. The TNM clinical staging system is used for mammary tumors in cats as well as in dogs.

A distinct entity called feline mammary hypertrophy has been noted in cats (see p 1396). It affects primarily young, actively cycling, or pregnant cats. It also has been seen in neutered cats, including older males given exogenous progestational drugs (megestrol acetate). The disorder is marked clinically by the rapid growth of one or more mammary glands.

Diagnosis: A mammary tumor is usually suspected on detection of a mass during physical examination. The length of time the mass has been present is usually unknown, but the rate of growth may be helpful in determining prognosis. Palpation of the regional lymph nodes can help determine the extent of spread. Thoracic radiographs, preferably three views (a ventral-dorsal and two laterals), should be taken to detect pulmonary metastases. Fine-needle aspirates may differentiate between inflammatory and neoplastic lesions but may lead to erroneous conclusions and delay of surgery. The diagnosis is determined by histopathology and is important in defining treatment and prognosis.

Treatment and Prognosis: Mammary tumors are treated surgically, although there is no consensus as to the best procedure. Removal of the tumor alone (lumpectomy), simple mastectomy (removal of the affected gland only), modified radical mastectomy (removal of the affected gland and those that share lymphatic drainage and associated lymph nodes), and radical mastectomy (removal of the entire mammary chain and associated lymph nodes) all have their proponents. In dogs, the more involved procedures have not prolonged survival compared with the others, and the advantages of the simpler procedures are obvious. In cats, radical mastectomy has increased the disease-free interval but not survival time.

In theory, the use of anticancer drugs to combat micrometastatic disease (adjuvant chemotherapy) is a reasonable consideration. However, chemotherapy has not been

shown to be an effective treatment for mammary tumors in dogs. Part of the difficulty of evaluating the response to adjuvant chemotherapy relates to the fact that only about half of the canine mammary tumors diagnosed as malignant on histopathologic examination actually behave that way. A combination of doxorubicin and cyclophosphamide has been used with limited efficacy in cats. Neither radiation therapy nor antiestrogenic compounds have been effective.

Use of the NSAID piroxicam (0.3 mg/kg/day, PO) as a single agent has been beneficial in treating inflammatory mammary carcinoma, a subtype of mammary tumor in dogs that has been very

difficult to manage by surgical or medical means. This is in step with current interest in metronomic low-dose therapy in other malignancies for an antitumor and anti-angiogenic effect.

The prognosis is based on multiple factors. In dogs, most mammary tumors that are going to cause death do so within 1 yr. Sarcomas are associated with shorter survival times than carcinomas. Other factors, including size of tumor, lymph node involvement, and nuclear differentiation, also affect the prognosis. In cats, tumor size is important; cats with tumors >3 cm in diameter have a median survival time of 6 mo, but cats with tumors <2 cm in diameter have a median survival time of >4 yr.

PROSTATIC DISEASES

Disease of the prostate gland is relatively common in intact dogs but less common in other domestic animal species. Benign prostatic hyperplasia is by far the most common disease of the prostate in intact male dogs. Bacterial prostatitis (acute or chronic), prostatic abscesses, prostatic and paraprostatic cysts, and prostatic adenocarcinoma are seen much less frequently and can be seen in castrated males. Depending on the disorder, clinical signs may include tenesmus during defecation, intermittent hematuria, recurrent urinary tract infections, and caudal abdominal discomfort. However, many intact males with benign prostatic hyperplasia (with or without chronic prostatitis) are asymptomatic or present with signs of hemospermia and/or infertility only. Additional nonspecific signs, such as fever, malaise, anorexia, severe stiffness, and caudal abdominal pain, can be seen with acute bacterial infections, abscesses, and neoplasia. Prostatic adenocarcinoma with bony involvement of the pelvis and lumbar vertebrae may cause hindlimb gait abnormalities. Less commonly, prostatic diseases may cause urinary incontinence. Prostatic adenocarcinoma may cause complete urethral obstruction.

Physical examination of the prostate gland should include abdominal and rectal palpation. An enlarged prostate typically is located further cranial than usual and can be found in the caudal abdomen rather than within the pelvic canal. Simultaneous abdominal and rectal palpation allows not

only for the cranial aspects of the prostate to be palpated but also for better palpation per rectum because the prostate can be pushed into or near the pelvic canal, which is especially important in large-breed dogs and in males with very enlarged prostates. Size, shape, symmetry, consistency, mobility, and the presence or absence of pain can be assessed by palpation. The normal dorsal sulcus (depression) aids in assessment of shape and symmetry.

Abdominal radiographs may help define the size, shape, and position of the prostate gland. The sublumbar lymph nodes, lumbar vertebrae, and bony pelvis should be evaluated radiographically for evidence of periosteal new bone and bony metastases. A positive-contrast retrograde urethrogram can be done when an abnormal prostate or paraprostatic cyst is difficult to differentiate from the bladder. However, transabdominal ultrasonography is the best imaging modality for evaluation of the prostate, because it allows for evaluation of the prostatic parenchyma and adjacent soft-tissue structures. Increased echogenicity is associated with benign prostatic hyperplasia, chronic bacterial prostatitis, and prostatic neoplasia, whereas areas of mineralization may be secondary to chronic bacterial prostatitis or prostatic neoplasia. Mass lesions within the prostatic urethra and discontinuity of the prostatic urethral wall are both highly suggestive of prostatic neoplasia.

If the dog will not ejaculate, material for cytologic and microbiologic examination

can be obtained by prostatic massage. Using aseptic technique, the bladder is catheterized, and all urine removed. The bladder is flushed with saline, and this sample is saved. The catheter is then withdrawn so that the end is caudal to the prostate. The prostate is subsequently massaged per rectum for about 1 minute to release prostatic fluid into the urethra, where it can be collected with the catheter. While occluding the urethral opening, saline is slowly injected. The catheter is then advanced into the bladder as aspiration is performed and another sample is collected. Results of cytologic and microbiologic examination from both prostatic wash specimens should be compared. Prostatic massage may produce septicemia in dogs with acute bacterial prostatitis or a prostatic abscess. Neoplastic cells are often not recovered in specimens obtained by ejaculation or prostatic massage.

Fine-needle aspiration of the prostate gland can be performed transrectally or percutaneously, with or without ultrasonographic guidance. While generally safe and simple, this is not without some risk of penetration of surrounding structures. Biopsy is the most definitive, but also the most invasive, diagnostic procedure to differentiate prostatic diseases. To obtain diagnostic samples, prostatic biopsy should be performed via celiotomy or by a skilled ultrasonographer.

BENIGN PROSTATIC HYPERPLASIA

Benign prostatic hyperplasia (BPH) is the most common prostatic disorder and is found in most intact male dogs >6 yr old as a result of androgenic stimulation or altered androgen:estrogen ratio. It is not known why some males are affected and others are not. In some dogs, hyperplasia may begin as early as 2.5 yr of age and, after 4 yr of age, cystic hyperplasia tends to develop. Clinical signs may be absent, or tenesmus, persistent or intermittent hematuria, or hemorrhagic preputial discharge may occur. The diagnosis is suggested by physical and historical findings and by a nonpainful, synunetrically enlarged prostate. Radiology can confirm prostatomegaly. Ultrasonography should show diffuse, relatively symmetric involvement with multiple, diffuse, cystic structures. Cytologic examination of massage or ejaculate specimens reveals hemorrhage with mild inflammation without evidence of sepsis or neoplasia. Definitive diagnosis is only possible by biopsy. Castration is the treatment of choice; prostatic involution is

usually evident within a few weeks and is often complete in several months.

For males intended for use in breeding, medical therapy with finasteride is effective. Finasteride blocks the action of 5 α -reductase, an enzyme that converts testosterone to dihydrotestosterone. Dihydrotestosterone is the biologically active hormone to promote prostatic hyperplasia in both people and dogs. Giving finasteride at 1 mg/kg/day, PO, for 16–21 wk, to laboratory Beagles resulted in a 50%–70% reduction in prostatic hypertrophy with no negative effect on semen quality. Lower dosages of finasteride (0.1 mg/kg/day, PO, for 16 wk) reduced hypertrophied prostate volume by 43%, resolved clinical signs, reduced dihydrotestosterone concentration by 58%, maintained normal testosterone levels, and had no deleterious effect on semen quality, fertility, or libido in a group of nine dogs with prostatic hypertrophy. However, prostatic hypertrophy returns if finasteride administration is discontinued. The low dosage (0.1–0.5 mg/kg) of finasteride correlates to convenient dosing of one 5-mg capsule/day for dogs weighing 10–50 kg.

PROSTATITIS

Inflammation of the canine prostate gland usually is suppurative, and acute prostatitis may result in abscesses. Chronic prostatitis occurs secondary to benign prostatic hyperplasia (see p 1406). Various organisms, including *Escherichia coli*, *Staphylococcus*, *Streptococcus*, and *Mycoplasma* spp, have been incriminated. Infection may be hematogenous (acute prostatitis) or ascend from the urethra (chronic prostatitis). Because prostatic fluid normally refluxes into the bladder, a secondary urinary tract infection often accompanies prostatic infection. Acute prostatitis and chronic prostatitis vary based on progression and severity of clinical signs.

Acute prostatitis is associated with malaise, pain, and fever. Dehydration, septicemia, and shock may occur in severe cases. Neutrophilia with a left shift, monocytosis, and/or toxic WBCs may be seen. Ultrasonography shows hypoechoic areas consistent with small pockets of fluid. Ideally, prostatic material is obtained by prostatic massage for cytologic examination and for culture and sensitivity testing. Massage of an acutely infected prostate may release organisms into the blood and cause septicemia. Urinalysis shows hematuria, pyuria, and bacteriuria. The urine should be submitted for culture and sensitivity testing. Often, the urine and prostatic material yield the same organisms.

IV fluid therapy is indicated when acute prostatitis is associated with dehydration or shock. Because the prostate-blood barrier is disrupted in acute prostatitis, antibiotics should be selected on the basis of sensitivity testing and given for 3–4 wk. Enrofloxacin at a dosage of 5 mg/kg, bid, orally is a good empiric treatment choice while awaiting results of microbiologic testing. After the infection is controlled, castration should be considered. In some instances, multiple microabscesses within an infected prostate gland may coalesce into a solitary abscess. Large prostatic abscesses are best treated by surgical drainage and intracapsular omentalization. Urine or prostatic fluid (or both) should be cultured again 2–4 wk after antibiotic therapy to be certain that infection has resolved.

Chronic bacterial prostatitis may cause no clinical signs except recurrent urinary tract infection. Physical abnormalities may be limited to the urinary tract. Rarely, prostatic size and shape may be normal. Microbiologic examination of the third (prostatic) fraction of the ejaculate is more accurate for assessment of chronic bacterial prostatitis than examination of prostatic massage specimens. Dogs with chronic bacterial prostatitis are usually willing to ejaculate. Prostatic fluid and urine should be submitted for cytologic and microbiologic examination.

Chronic bacterial prostatitis will not resolve without also treating for benign prostatic hyperplasia. In fact, most cases of chronic bacterial prostatitis will resolve with only treatment for benign prostatic hyperplasia, whether surgical (castration) or medical (finasteride). Antibiotic therapy alone is unrewarding. Many antibiotics do not diffuse easily into the prostatic parenchyma because of the presence of the blood-prostate barrier. The mild inflammation associated with chronic prostatitis may not impair the blood-prostate barrier, so antibiotics that are non-ionized at neutral pH with high fat solubility (eg, erythromycin, clindamycin, trimethoprim-sulfamethoxazole, or enrofloxacin) are most effective. If antibiotic therapy is implemented, it should be continued for ≥ 4 wk.

PROSTATIC AND PARAPROSTATIC CYSTS

Large cysts are occasionally found within or adjacent to (paraprostatic) the prostate gland. Paraprostatic cysts result from embryologic remnants of the female reproductive tract found in males that become fluid-filled. The signs are similar

to those seen with other types of prostatic enlargement and usually become apparent only when the cyst reaches a size sufficient to cause pressure on adjacent organs. Large cysts may result in abdominal distention and must be differentiated from the bladder and from prostatic abscesses.

Medical treatment is ineffective. Castration alone is unlikely to be of benefit but may be indicated after the cyst has been removed. Total excision of the prostatic cyst is the treatment of choice. If complete excision of the cyst is not possible, the remaining portion of the cyst may be filled with a leaf of omentum secured with sutures. This “omentalization” of the cyst will provide internal drainage and lead to resolution. Surgical excision is preferable to marsupialization, because chronic management of the marsupialization fistula is often problematic.

NEOPLASMS

The most common neoplasm of the prostate is carcinoma arising from ductal or urothelial tissue. Transitional cell carcinoma arising from the prostatic urethra occasionally invades the prostate. Not only does castration not protect against future development of prostatic neoplasia in dogs, but incidence of prostatic neoplasia is higher in castrated dogs.

The clinical signs of prostatic neoplasia may be similar to those of other prostatic diseases. Pain and fever may be present. If the neoplasm infiltrates the urethra, dysuria or urethral obstruction is likely. On rectal palpation, the prostate may be normal in size but feel asymmetrical and nodular. It may also be firmly adhered to the pelvic floor or adjacent structures. Ultrasonographic examination may show an irregularly shaped prostate gland with hyperechoic, heterogeneous foci. Gross metastases are present at the time of diagnosis in $>80\%$ of dogs with prostatic carcinoma. The most common sites of metastases are the regional lymph nodes, lumbar vertebrae, and bony pelvis. Spread to distant sites (such as the lungs) is uncommon until late in the course of disease. Urethral obstruction caused by prostatic disease in dogs is highly suggestive of neoplasia, as is prostatomegaly in a previously castrated dog. Diagnosis is made by biopsy. Prostatic tumor markers used for human prostatic cancer, such as prostate-specific antigen or prostatic acid phosphatase, are not present in canine prostate glands.

There is no effective curative treatment for prostatic carcinoma in dogs. Because of

the high incidence of metastases at the time of diagnosis, and the high incidence of urinary incontinence after prostatectomy in dogs, total prostatectomy is not recommended as a treatment. Radiation therapy for prostatic cancer often results in incontinence due to radiation-induced fibrosis of the urinary bladder. Alternative means of ablating prostatic tissue such as transrectal high-intensity focused ultrasound, transurethral intraprostatic absolute ethanol injections, transurethral laser vaporization, or transurethral electrocoagulation have been successful in experimental studies but have not been performed on dogs with prostatic carcinoma. A relatively simple treatment

offered some efficacy for dogs with prostatic carcinoma in one study involving 32 dogs. Treatment with the cyclooxygenase inhibitors piroxicam (0.3 mg/kg/day, PO) or carprofen (2.2 mg/kg, PO, bid) significantly prolonged the median survival time of dogs with prostatic carcinoma compared with dogs receiving no treatment (6.9 vs 0.7 mo).

PROSTATIC CALCULI

When prostatic calculi occur (rarely), there is usually some other prostatic disease as well. Rarely, radiopaque prostatic calculi are incidental findings on abdominal radiographs.

CANINE TRANSMISSIBLE VENEREAL TUMOR

Canine transmissible venereal tumors (TVTs) are cauliflower-like, pedunculated, nodular, papillary, or multilobulated in appearance. They range in size from a small nodule (5 mm) to a large mass (>10 cm) that is firm, though friable. The surface is often ulcerated and inflamed and bleeds easily. TVTs may be solitary or multiple and are almost always located on the genitalia. The tumor is transplanted from site to site and from dog to dog by direct contact with the mass. They may be transplanted to adjacent skin and oral, nasal, or conjunctival mucosae. The tumor may arise deep within the preputial, vaginal, or nasal cavity and be difficult to see during cursory examination. This may lead to misdiagnosis if bleeding is incorrectly assumed to be hematuria or epistaxis from other causes. Initially, TVTs grow rapidly, and more rapidly in neonatal and immunosuppressed dogs. Metastasis is uncommon (5%) and can occur without a primary genital tumor present. When metastasis occurs, it is usually to the regional lymph nodes, but kidney, spleen, eye, brain, pituitary, skin and subcutis, mesenteric lymph nodes, and peritoneum may also be sites.

Because of their homogenous populations of large, round cells with distinctive centrally located nucleoli, TVTs are usually easily diagnosed by cytologic examination of fine-needle aspirates or impression smears or by histopathologic evaluation of

biopsies. TVTs may be difficult to distinguish from other round cell tumors, particularly lymphosarcomas, when they occur in extragenital locations. Although TVT has a worldwide distribution, prevalence varies from relatively high in some geographic regions (eg, tropical and subtropical urban environments) to rare in others.

Although spontaneous regression can occur, TVTs are usually progressive and treated accordingly. Complete surgical excision, radiation therapy, and chemotherapy are effective treatments; however, chemotherapy is considered the treatment of choice. Vincristine sulfate (0.5–0.7 mg/m², IV, once weekly for 3–6 wk) is reported to be effective. The rate of tumor regression is negatively correlated with tumor size, older age, and season. Usually, total remission can be expected by the sixth treatment. Adriamycin (30 mg/m² for dogs weighing >10 kg; 1 mg/kg for dogs weighing ≤10 kg; IV, once every 3 wk) and radiation therapy have been effective for those animals that do not respond to vincristine.

The prognosis for total remission with chemotherapy or radiation therapy is good, unless there is metastatic involvement of organs other than skin. Complete surgical excision often cannot be achieved because of the anatomic location of many of these tumors. Recurrence is likely in such cases unless adjunct radiation or chemotherapy is used.

RESPIRATORY SYSTEM INTRODUCTION

The respiratory system performs several functions. Most importantly, it delivers oxygen to the cardiovascular system for distribution to the body and it removes carbon dioxide. Gas transfer occurs in the alveoli of the lungs, where the air-blood barrier is a thin, permeable membrane. Failure or major dysfunction of gas transfer due to disease processes that compromise this membrane or its air or blood supply have serious effects. In addition to gas exchange, the respiratory system performs numerous other functions, including maintaining acid-base balance, acting as a blood reservoir, filtering and probably destroying emboli, metabolizing some bioactive substances (eg, serotonin, prostaglandins, corticosteroids, and leukotrienes), and activating some substances (eg, angiotensin). The respiratory system also protects its own delicate airways by warming and humidifying inhaled air and by filtering out

particulate material. The upper airways also provide for the sense of smell (olfaction) and play a role in temperature regulation in panting animals.

Large, airborne particles are usually deposited on the mucous lining of the nasal passages, larynx, trachea, and bronchi, after which they are carried by the mucociliary “blanket” to the pharynx to be swallowed or expectorated. Small particles may be deposited as deep as the alveoli, where they are phagocytized by macrophages. Defense against invasion by microorganisms and other foreign particles is provided by anatomic structures and by both nonspecific and immunologic mechanisms (both cellular and humoral). These are the factors that determine species and individual susceptibility to disease and that may be manipulated by using various management techniques, vaccines, antimicrobials, and other agents such as interferons and

lymphokines. Other mechanical factors include the tortuosity of nasal passages; presence of hairs, cilia, and mucus; the cough reflex; and bronchoconstriction. Cellular defenses include macrophages, which phagocytize invaders and present them (or at least their important antigens) to lymphocytes for stimulation of an immune response, and neutrophils, which often die in their fight against invaders and must be removed along with their potentially damaging enzymes. Secretory defenses include interferon for antiviral defense, complement for lysis of invaders, surfactant lining the alveoli to prevent their collapse and to facilitate macrophage function, fibronectin to modulate bacterial attachment, antibodies, and mucus.

The respiratory system must perform many functions, preferably while expending minimal energy. The required effort is increased by processes that oppose expansion of the lung (eg, fibrosis or hydro-, chylo-, pneumo-, or hemothorax), impede the flow of air (eg, obstructive nasal disease, bronchiolitis, bronchoconstriction, laryngeal paralysis, or pulmonary edema), or thicken the air-blood interface (eg, interstitial pneumonia due to viruses or toxins, pulmonary edema).

The anatomy of the respiratory tract differs markedly among species in the following features: 1) shape of both the upper and lower respiratory tract; 2) extent, shape, and pattern of the turbinate bones; 3) branching patterns of bronchi; 4) anatomy of terminal bronchioles, including collateral ventilation; 5) lobation and lobulation; 6) thickness of pleura; 7) completeness of the mediastinum; 8) relationship of pulmonary arteries to bronchial arteries and bronchioles; 9) presence of vascular shunts; 10) distribution of mast cells; and 11) blood supply to the pleura. Each variation in anatomic structure implies variation in function, which can influence the pathogenesis of respiratory disease in a particular species. The three main groups of species that have similar subgross anatomy of the lung are 1) cattle, sheep, and pigs; 2) dogs, cats, monkeys, rats, rabbits, and guinea pigs; and 3) horses and people.

Marked physiologic variations also exist between different species. For example, cattle are prone to retrograde drainage from the pharynx, are predisposed to pulmonary hypertension and reduced ventilation in a cold environment, have relatively small lungs with low tidal volume and functional residual capacity, and are more sensitive to changes in environmental temperatures than are most other species. These anatomic and

physiologic differences largely determine why some pathogens affect only some species (eg, *Mannheimia haemolytica* affects cattle but not pigs) and why pneumonia is very important in some species (cattle, pigs) but less so in others (dogs, cats).

Hypoxia (lowered oxygenation, often termed anoxia) causes clinical signs of respiratory disease. It can result from the following: 1) reduced oxygen-carrying capacity of the blood (anemic anoxia, as in carbon monoxide or nitrite poisoning, or true anemia due to various causes); 2) reduced blood flow (stagnant anoxia, as in congestive heart failure or shock); 3) insufficient alveolar ventilation, mismatching between ventilation and perfusion, shunt or diffusion impairment (hypoxic anoxia, as in pneumonia, pulmonary edema, chronic congestion, pneumothorax, or paralysis of respiratory muscles); or 4) inability of tissues to use available oxygen (eg, histotoxic anoxia, as in cyanide poisoning).

Compensatory mechanisms for hypoxia include increased depth and rate of breathing, which is mediated by chemoreceptors located in the carotid and aortic bodies; contraction of the spleen, which forces more RBCs into the circulation; and increased cardiac stroke volume and heart rate. If cerebral hypoxia develops, respiratory function may be reduced even further due to depression of neuronal activity. Erythropoiesis is also stimulated with chronic hypoxia, although the degree of polycythemia is species dependent. In addition, myocardial, renal, and hepatic functions may be reduced, as may motility and secretions of the intestine. If compensatory mechanisms are inadequate, a vicious cycle may begin in which all body tissues function less efficiently.

CLINICAL SIGNS OF RESPIRATORY MALFUNCTION

Nasal discharge may be serous, catarrhal, purulent, or hemorrhagic, depending on the degree of mucosal or turbinate damage. It indicates increased production of normal secretions, sometimes supplemented by neutrophils (purulent) or blood (hemorrhage). It probably also indicates decreased "grooming" of the nostrils with the tongue when animals are ill. **Epistaxis** (bleeding from the nose) is often caused by vascular rupture, such as in mycotic infection of the guttural pouch or exercise-induced pulmonary hemorrhage in horses, or by intranasal fungal infection or neoplasia,

systemic coagulopathy, vasculitis, thrombocytopenia (immune-mediated or a result of rickettsial infection), hyperviscosity syndrome, hypertension, or nasal trauma. **Hemoptysis** (the coughing up of blood) occurs after rupture of pulmonary aneurysms in the lungs of cattle with chronic lung abscesses. Bleeding may also result from polyps, neoplasms, granulomas, trauma, thrombocytopenia, and bracken fern or sweet clover toxicity.

Hyperpnea (an increase in rate and depth of breathing) becomes **dyspnea** when the breathing appears to be labored and causing distress. Hyperpnea, however, is not always a sign of disease (eg, labored breathing after vigorous exercise in an otherwise healthy animal). Infectious respiratory diseases that cause toxemia may further compromise the host, eg, bovine pneumonia due to *M haemolytica*. Dyspnea can be caused by disease of the respiratory tract itself (eg, airway obstruction, pneumonia, bronchitis, or alveolitis) or by other problems (eg, heart failure, acid-base imbalances, thoracic effusions, abnormal oxygen-carrying capacity of the blood, or disorders of neuromuscular function). Labored inhalation seen with obstructive diseases above the thoracic inlet (eg, laryngeal paralysis, cervical tracheal collapse) or with pleural effusions is termed inspiratory dyspnea; labored expiration seen with obstructive diseases below the thoracic inlet (eg, diffuse bronchitis, principal bronchial collapse, or pulmonary edema) is termed expiratory dyspnea. Fixed airway obstructions (eg, tracheal neoplasia, foreign body, or stenosis) or a combination of upper and lower obstructive airway diseases (eg, pleural effusion with congestive heart failure) result in both inspiratory and expiratory dyspnea. Other responses include coughing, clear exudates, and shallow breathing with grunting, often associated with the pain of pleuritis.

CAUSES OF RESPIRATORY MALFUNCTION

Congenital anomalies of the respiratory tract are rare but do occur. Examples include cysts in the sinuses and turbinates, tracheal hypoplasia, nasopharyngeal turbinates, and accessory lungs. A common cause of upper respiratory tract malfunction is **rhinitis** (which results in exudation of neutrophils, macrophages, and fluids), or erosion and ulceration (or both) of the nasal mucosa. It may be caused by viral, bacterial, fungal, or parasitic agents, as well as by hypersensitivity reactions, such

as localized allergies and anaphylaxis (see p 811). Atrophy of the turbinates (eg, in atrophic rhinitis of pigs) removes a major filtration function and exposes the lungs to much heavier loads of dust and microorganisms. The nasal cavity may be obstructed by tumors, granulomas, abscesses, or foreign bodies. Sinusitis can be a complication of upper respiratory infections, tooth root infection, or dehorming.

Laryngitis, tracheitis, and bronchitis result in coughing and possibly inspiratory or expiratory dyspnea. Coughing may be nonproductive if the irritation is caused by mucosal erosion, or productive if caused by copious exudate in the major airways. Severe pulmonary edema and emphysema cause extreme respiratory insufficiency.

The most common respiratory disease is **pneumonia**, which is defined as inflammation of the lungs. There are many systems to classify the various types of pneumonia. One useful method is to classify according to the distribution of lesions in the lungs. **Focal pneumonia** has one or more discrete foci in a random pattern, eg, abscessation due to emboli from other sites, tuberculosis, or actinomycosis. **Lobular pneumonia** accentuates the anatomic pattern of lobules, as in bronchopneumonia caused by *Pasteurella multocida*. **Lobar pneumonia** covers large areas of lobes and is often severe (eg, fibrinous pneumonic pasteurellosis of cattle). **Diffuse or interstitial pneumonia** often involves the entire lung, as in maedi of sheep or in hypersensitivity reactions. The appearance or cause of a particular pneumonia can be described further, eg, gangrenous, parasitic (verminous), aspiration, etc.

Infection may develop as a result of one or a combination of factors: 1) defense mechanisms are overwhelmed, 2) the infectious agent is highly virulent, 3) the size of the inoculum is large, and/or 4) the animal's defense mechanisms are compromised. The initial problem in many pneumonias is thought to be a sudden change in the normal nasal bacterial flora, which results in a sudden dramatic increase in one or more species of bacteria. Bacterial proliferation is usually caused by a breakdown of the host defenses as a result of stress (eg, transportation, concurrent illness) or cellular insult (eg, viral infection, toxicity). These bacteria are breathed into the lung in large numbers and may overwhelm the normal defense mechanisms, localize, multiply, and initiate inflammation. In addition, stress is often a precursor of viral respiratory infections, particularly in groups of animals that have recently been

congregated and stressed by travel, handling, and mixing. Some respiratory viral infections can cause temporary dysfunction of phagocytic mechanisms of the alveolar macrophages. This usually occurs several days after viral exposure. Inhaled bacteria proliferate and pneumonia ensues, often with an overwhelming infection and massive exudation into the alveoli.

Pneumonia also can be caused by direct infection with viruses, bacteria, and fungi, as well as by toxins arriving hematogenously, by inhalation, or by aspiration of food or gastric contents.

Through natural processes, possibly aided by appropriate therapy, the exudate may be removed from the lungs, and the mucosal lesions of the air passages may heal.

However, serious sequelae can persist. **Bronchiectasis** is a chronic lesion of the bronchi and parenchyma characterized by irreversible cylindrical or saccular dilatation, secondary infection, and atelectasis. Ulceration of bronchioles caused by viral agents may lead to organized plugs of connective tissue in small bronchioles, a lesion called **bronchiolitis obliterans**, which may cause permanent obstruction, atelectasis, and severe respiratory insufficiency. Constriction of bronchi and bronchioles in chronic allergic bronchitis and bronchiolitis results in similar clinical signs. However, administration of bronchodilators results in rapid relief of airway obstruction in cases of allergic bronchitis (eg, heaves in horses). Some chronic pneumonias (eg, maedi in sheep) are characterized by firm diffuse lesions due to hyperplasia of lymphoid follicles, hyperplasia of smooth muscle around bronchioles, diffuse fibrosis, and diffuse lymphocytic infiltration. Aspiration pneumonia often leads to gangrene, with severe toxemia accompanying the acute inflammatory reaction.

Most infectious pneumonias develop in the anteroventral portions of the lungs. However, infectious agents, as well as neoplasms, can invade the lungs via the blood, which may extensively impair pulmonary function, as can pulmonary edema from chronic heart failure. Pleuritis, empyema, hydrothorax, chylothorax, atelectasis, diaphragmatic hernia, or pneumothorax can also seriously impair respiratory function. Pulmonary thrombosis leads to acute, often fulminant, respiratory failure as a result of a lack of pulmonary arterial blood flow to ventilated regions of the lung. Infarction of the lung can reduce respiratory function but is rare because of the dual blood supply of the organ. Toxic injury, such as in 3-methylindole toxicity

in cattle, causes edema, emphysema, and necrosis of alveolar epithelium, followed by compensatory hyperplasia of these cells; the effects on gas exchange result in severe hypoxia and dyspnea.

Although pneumonia is most important, several other thoracic conditions can cause respiratory dysfunction. **Pulmonary edema**, the abnormal accumulation of fluid in the interstitial tissue, airways, or alveoli of the lungs, may occur in conjunction with circulatory disorders, particularly left ventricular failure or increased capillary permeability, occasionally in anaphylactic and allergic reactions, and in some infectious diseases. Head trauma can cause pulmonary edema in dogs. Dyspnea and open-mouth breathing may occur. Animals stand in preference to lying down, lie only in sternal recumbency, or may assume a sitting position. Auscultation of the chest may reveal wheezing and fluid sounds.

Pleuritis (pleurisy) may be caused by any pathogen that gains entrance to the pleural cavity, but it is often an extension of pneumonia. Rapid shallow breathing, fever, and thoracic pain are suggestive of pleuritis. Auscultation of the chest may reveal friction sounds.

Empyema (purulent exudate in the pleural cavity) is caused by pyogenic bacteria or fungi reaching the thoracic cavity via the blood or by extension of a pneumonia, traumatic reticulitis, or penetrating wound of the chest. Cough, fever, pain, and dyspnea may be present.

Hemothorax (the accumulation of blood in the pleural cavity) is usually caused by trauma to the thorax, systemic coagulopathy, or thoracic neoplasia. **Hydrothorax** (the accumulation of transudate in the pleural cavity) is usually due to interference with venous blood flow or lymph drainage. **Chylothorax** (the accumulation of chyle in the pleural cavity) is relatively rare and is seen most often in cats. It may be caused by rupture of the thoracic duct but often is idiopathic. The signs of all three conditions include respiratory embarrassment (eg, rapid shallow breathing with inspiratory dyspnea) and weakness.

Pneumothorax (air in the pleural cavity, see p 1664) may be of traumatic or spontaneous origin. Air can enter the pleural cavity through penetrating wounds of the thoracic wall or by extension from pulmonary emphysema or ruptured bullae. The lung collapses if a large volume of air enters the pleural cavity. Bilateral pneumothorax may develop if the mediastinum is weak or incomplete. Inspiratory dyspnea or rapid, shallow breathing is evident.

DIAGNOSTIC TECHNIQUES

Clinical history and physical examination should help to determine the possible cause and site of respiratory disease. Lateral cervical and thoracic radiographs may be helpful when obstructive upper airway disease or fixed airway obstruction is suspected (eg, tracheal foreign body, masses, foreign bodies, or stenosis). Thoracic radiographs are essential in any animal exhibiting lower respiratory signs (eg, cough, rapid shallow breathing, dyspnea), but diagnostic value may be limited in animals that have a large thorax (eg, adult horses or cattle). Arterial blood gas analysis or pulse oximetry may help assess the need for oxygen therapy in an animal with severe dyspnea.

When obstructive upper airway disease is suspected, the diagnostic procedure of choice is endoscopy of the respiratory tract, preferably without sedation. Laryngeal function should be assessed, and the presence of obstructive lesions within the nasopharynx, oropharynx, larynx, trachea, or principal bronchi should be identified.

With diffuse or lobar lung disease, diagnostic procedures include transtracheal wash, bronchoscopy with bronchoalveolar lavage or endobronchial biopsy, and transthoracic fine-needle aspirates of lung or lung biopsy. When bacterial pneumonia is suspected, bacterial culture of transtracheal wash is recommended. Cytologic evaluation of transtracheal or bronchoalveolar lavage fluid may aid in the diagnosis of fungal, parasitic, or allergic lung diseases. Transthoracic fine-needle aspirates of lung often are useful in the diagnosis of fungal pneumonia but have lower yields in the definitive diagnosis of solitary pulmonary lesions. Solitary pulmonary masses often require transthoracic lung biopsy or surgical excision for definitive diagnosis. Transthoracic ultrasonography is a sensitive diagnostic tool for pleural disease (eg, pleural effusion, pneumothorax) and for parenchymal lung disease when lesions are adjacent to the pleural surface.

In dogs or cats with pleural effusions, thoracocentesis should be performed for cytologic and potentially microbiologic evaluation of fluid. In cats, pleural effusions often occur with cardiac disease, so an echocardiography should be performed. In animals suspected to have a chylous effusion, serum and fluid triglyceride levels should be determined. Chylous effusions are associated with fluid triglyceride levels greater than that in serum.

Acute nasal discharge, sneezing, or both, may suggest the presence of infection (viral or bacterial) or a nasal foreign body. Chronic nasal discharge warrants further investigation via radiography (nose, guttural pouches in horses), nasal CT, rhinoscopy, nasopharyngoscopy, or nasal biopsy. Rhinoscopy may be of limited value if copious thick discharge or hemorrhage is present. Bacterial cultures of nasal tissue may be of value if bacterial rhinitis is suspected; however, in some species (eg, dogs and cats) primary bacterial rhinitis is rare and typically occurs secondary to other nasal conditions. Cytologic evaluation of nasal tissue may help diagnose nasal fungal infections. Serologic testing for fungal respiratory infections may be considered, but these findings should correlate with the animal's clinical signs and documentation of the presence of fungal organisms because false-positive and false-negative tests can occur.

CONTROL OF RESPIRATORY DISEASE

Sudden dietary changes, weaning, cold, drafts, dampness, dust, high levels of ammonia, poor ventilation in general, and the mixing of widely divergent age groups all play a role in respiratory disease in groups of animals. Stress and mixing of animals from several sources should be avoided or minimized. Establishing individual animal identification, making accurate clinical and postmortem diagnoses, and maintaining a record system of diagnosis and treatment are important to minimize or control outbreaks of pneumonia. Transportation over long distances is another stress factor that plays a major role in the pathogenesis of respiratory infections in large animals.

Immunization can help control respiratory infection. However, control may be compromised by improper timing, use of ineffective or inappropriate vaccines, or overwhelmingly negative management practices. In most cases, severe insults to the natural defenses cannot be reversed later by therapeutic agents and biologicals.

The mucosal surfaces of the respiratory tract contain lymphoid follicles that exchange cells with other parts of the body. However, most of the lymphocytes in the respiratory lining produce only IgA, whereas the cells in the lymph nodes of the respiratory tract produce IgM and IgG. Depending on the agent involved, various cell- and antibody-mediated immune

responses occur in the respiratory tract and include opsonization, agglutination, immobilization, neutralization of toxins and viruses, blockage of adherence to cells, lysis, and chemotaxis. The type of immune response varies because of age, species, and the means to respond to specific virulence mechanisms of the pathogens involved.

Species vary in the type of immune response available at different sites in the respiratory tract. Large antigen droplets may immunize the upper tract with IgA, but small replicating particles may be necessary to immunize the lower tract. To develop adequate antibody levels to protect the lungs, repeated doses of antigen plus adjuvant, or a replicating antigen, are often necessary. These results are seldom achieved under field conditions (eg, many field trials using respiratory vaccines in cattle have not demonstrated statistically significant efficacy).

Environmental management is an essential part of therapy in allergic respiratory diseases. For example, clinical signs in horses with heaves (recurrent airway obstruction, *see* p 1455) or cattle with hypersensitivity pneumonitis (*see* p 1441) may be effectively controlled by preventing exposure to molds present in hay.

PRINCIPLES OF THERAPY

See also SYSTEMIC PHARMACOTHERAPEUTICS OF THE RESPIRATORY SYSTEM, p 2608.

Respiratory disease is often characterized by abnormal production of secretions and exudates and by a reduced ability to remove them. The primary goal of therapy is to reduce the volume and viscosity of the secretions and to facilitate their removal. This can be accomplished by controlling infection and inflammation, modifying the secretions, and when possible, improving postural drainage and mechanically removing the material. Therapeutic methods include altering the inspired air and administering expectorants, antitussives, bronchodilators, antimicrobials, diuretics, and other drugs. However, expectorants have shown little or no beneficial effects in clinical trials.

Hydration should be maintained. Inhalation of humidified air may facilitate removal of airway secretions. Expectorants are sometimes used with the intention of liquefying these secretions. However, they should be used in conjunction with ancillary respiratory therapy such as improved postural drainage, mild exercise, and thoracic percussion, which (in addition to coughing) encourages expectoration and removal of secretions. Mechanical removal

of tenacious and viscid secretions by aspiration may be necessary in severe airway obstruction.

Antitussive agents are indicated to relieve the discomfort associated with nonproductive coughing but are contraindicated when secretion of airway mucus is excessive. Products that contain atropine also are contraindicated, at least in theory, because atropine increases the viscosity of airway secretions.

Increased airway resistance caused by bronchial smooth muscle contraction can be alleviated with bronchodilators, which may be indicated in animals with asthma-like conditions and chronic respiratory disease. Methylxanthines, such as theophylline and aminophylline, are effective bronchodilators in species other than cattle (and possibly dogs); however, the therapeutic index is relatively narrow and they are less efficacious than β_2 -agonists. Isoproterenol, clenbuterol, and epinephrine are also generally effective, and sodium cromoglycate may be used in horses with inflammatory airway disease. Corticosteroids are highly effective in allergic conditions, but systemic use may result in adverse effects. Aerosolized corticosteroids are efficacious and associated with few to no adverse effects; however, they require an aerosol delivery device (eg, face mask) for proper administration. Antihistamines can be used to alleviate the bronchoconstriction caused by histamine release; however, they are of limited value in large animals. Bronchospasm also can be reduced significantly by removing irritating factors, using mild sedatives, or reducing periods of excitement.

In bacterial infection, antimicrobial therapy should be instituted. The goal is to select either the most effective agent against a specific organism or the least toxic agent of several alternatives. Culture and sensitivity testing of airway secretions provide a worthwhile, although not infallible, guide to determining the appropriate antibiotic. Knowledge of tissue penetration and pharmacokinetic characteristics of the antimicrobial agents is important as well. The following agents have proved effective in the listed species: cattle—oxytetracycline, cephalosporins, fluoroquinolones, macrolides, florfenicol, penicillins, and sulfonamides; sheep and goats—oxytetracycline, cephalosporins, macrolides, penicillins, and sulfonamides; pigs—lincomycin, spectinomycin, penicillins, and sulfonamides; dogs and cats—cephalosporins, chloramphenicol, amoxicillin-clavulanate, aminoglycosides, trimethoprim-sulfamethoxazole,

fluoroquinolones, macrolides, and tetracyclines; horses—penicillins, aminoglycosides, cephalosporins, fluoroquinolones, sulfonamides, and tetracyclines (the latter with caution due to an occasional adverse effect of severe diarrhea). Aminoglycosides are useful but can be nephrotoxic. Trimethoprim, usually in combination with a sulfonamide, is useful for respiratory therapy in most species but is not licensed for food-producing animals in the USA. Drugs such as enrofloxacin (approved for small animals and cattle but not for horses in the USA) and ceftiofur are effective for pneumonia.

Broad-spectrum antibiotics should be used if specific bacteria cannot be identified, and once begun, a full course of therapy should be completed. Multiple antimicrobial agents should be used only with full knowledge of the potential drug interactions. Because of residues in food-producing animals, veterinarians must use these products according to label instructions and provide sound advice to producers. Extra-label use of antimicrobi-

als is permitted in some situations and is regulated by the Animal Medicinal Drug Use Clarification Act of 1994.

The hypoxemia caused by most lung disorders usually can be corrected by administering oxygen. However, continuous administration of high concentrations increases the tendency for regional resorption atelectasis, thus worsening the hypoxemia, and can cause pneumonitis on its own. Hypoxemia is often accompanied by variable degrees of hypercapnia and acidemia. Endotracheal intubation and mechanical ventilation may be necessary in animals with acute respiratory failure or in animals that are comatose or apneic. Arterial blood gas and pH determinations, when practicable, are extremely valuable to monitor treatment.

Diuretics are indicated in pulmonary edema. The osmotic diuretics have a minimal action on diuresis, carbonic anhydrase inhibitors (eg, acetazolamide) have a moderate effect, and loop diuretics (eg, furosemide) have a profound effect.

ASPIRATION PNEUMONIA

(Foreign-body pneumonia, Inhalation pneumonia, Gangrenous pneumonia)

Aspiration pneumonia is a pulmonary infection characterized by inflammation and necrosis due to inhalation of foreign material. The severity of the inflammatory response depends on the material aspirated, the type of bacteria aspirated, and the distribution of aspirated material in the lungs.

Etiology: Inappropriate administration of therapeutic agents is a common cause of aspiration pneumonia in large animals and less common in dogs and cats. Liquids given by drench or dose syringe should not be delivered faster than the animal can swallow. **■** Retching is particularly dangerous when the animal's tongue is drawn out, when the head is held high, or when the animal is coughing or bellowing.

In sheep, poor dipping technique with repeated immersion of the animal's head may cause aspiration of fluid. Calves and lambs may inhale inflammatory debris if affected with diphtheritic stomatitis/laryngitis. The muscles of deglutition may be affected in lambs with nutritional myopathy. Pigs fed

fine particulate food in dry environments may inhale feed granules. Aspiration pneumonia in cattle after treatment for milk fever is usually fatal. Cervids affected with chronic wasting disease may develop aspiration pneumonia due to CNS dysfunction. In dogs and less frequently in cats, aspiration pneumonia is generally associated with inhalation of oral ingesta, regurgitated material, or vomitus. Common risk factors for dogs and cats include pharyngeal abnormalities (cricopharyngeal motor dysfunction), esophageal diseases (megaeosophagus, gastroesophageal reflux disease, esophageal obstruction), weakened clinical condition, and anesthesia or heavy sedation. Bacteria in aspirated material may initiate acute infection or secondary infection later in disease.

Clinical Findings: A history suggesting recent foreign body aspiration within the past 1–2 days is of greatest value for a diagnosis of aspiration pneumonia. Affected animals separate from the rest

of the group and present with pyrexia 104°–105°F (40°–40.5°C), a painful expression, arched back, inappetence, depression, toxic mucous membranes, and an increased respiratory rate (>40–60 breaths/min) with a shallow abdominal component. This is often associated with a purulent nasal discharge that sometimes is tinged reddish brown or green. Milk yield is greatly reduced to zero in lactating animals. Thoracic auscultation reveals reduced lung sounds over affected consolidated lung, with increased breath sounds over normal lung. In cows that aspirate ruminal contents as a consequence of becoming cast with hypocalcemia, toxemia is usually fatal within 1–2 days.

Superficial consolidated lung and overlying lesions of fibrous pleurisy can readily be identified on ultrasound examination using either linear or sector probes connected to 5-MHz machines; pleuritic friction rubs are not audible on auscultation. In dogs and cats, clinical signs may be peracute, acute, or chronic. Cough, dyspnea, tachypnea, or exercise intolerance are seen most frequently. Thoracic radiographs generally show a bronchoalveolar pattern in gravity-dependent ventral lung lobes (right cranial and middle and left cranial lobes); however, radiographic changes may not be seen until 24 hr after acute aspiration.

Lesions: Aspiration pneumonia is usually in the anteroventral parts of the

lung; it may be unilateral in animals in which lateral recumbency was the cause of aspiration, or bilateral and centered on airways. In early stages, the lungs are markedly congested with areas of interlobular edema. Bronchi are hyperemic and full of froth. The pneumonic areas tend to be cone-shaped, with the base toward the pleura. Suppuration and necrosis follow. The foci become soft or liquefied, reddish brown, and foul smelling. There usually is an acute fibrinous pleuritis, often with pleural exudate. Animals that survive develop chronic abscesses and fibrous adhesions between the visceral and parietal pleura.

Prevention and Treatment: Broad-spectrum antibiotics should be used in animals known to have inhaled a foreign substance without waiting for signs of pneumonia to appear; however, this rarely occurs in farm animals presented with severe clinical signs. A transtracheal wash can help identify the causative agent for which an antibiotic sensitivity can be obtained. Care and supportive treatment include NSAIDs such as flunixin meglumine. In small animals, oxygen therapy can be useful. Saline nebulization and coughage may assist with generating a productive cough to facilitate clearance of the aspirated material. Despite all treatments, prognosis is poor, and efforts must be directed at prevention.

DIAPHRAGMATIC HERNIA

A break in the continuity of the diaphragm allows protrusion of abdominal viscera into the thorax.

Etiology: In small animals, automobile-related trauma is a common cause of diaphragmatic hernia, although congenital defects of the diaphragm may also result in herniation (eg, peritoneopericardial hernia). In horses, diaphragmatic hernia may occur, less commonly, congenitally or after trauma, dystocia, or recent strenuous activity. Diaphragmatic hernias are extremely rare in cattle.

Clinical Findings: The signs vary, depending on the duration and species

affected. Dogs and cats are characteristically dyspneic in the acute case. The degree of dyspnea may vary from subclinical to incompatible with life, depending on the amount of herniated viscera. If the stomach is herniated, it may bloat and the animal may deteriorate rapidly. In chronic cases, systemic signs such as weight loss may be more prominent than respiratory signs. Physical examination findings may include the absence of lung sounds and/or the presence of GI sounds on auscultation of the thorax. Congenital peritoneopericardial hernia is most frequently an incidental finding, although findings may be related to the respiratory or GI systems or due to compromised venous return to the heart.

Horses most frequently present with acute, severe colic secondary to displaced intestines, or with respiratory signs and dyspnea. In cattle and water buffalo, diaphragmatic hernias may be associated with traumatic reticulitis and herniation of the reticulum.

Diagnosis: Careful physical examination, including auscultation and percussion, usually suggests the presence of thoracic disease. The definitive diagnosis is most frequently made from radiographs. Loss of diaphragmatic contour, abdominal viscera in the thorax, and displacement of viscera from the abdomen may be apparent. Radiographic contrast studies may be necessary to make the diagnosis. Barium may be given by mouth (GI series),

or water-soluble contrast may be injected intraperitoneally (celiogram). Radiographs may be difficult to obtain in horses and cows; ultrasonography is useful. Samples from abdominocentesis and thoracocentesis, electrocardiographs, and blood work may be obtained, and surgical exploration of the abdominal cavity may be necessary for definitive diagnosis in these species.

Treatment: Surgical repair of the hernia is the preferred treatment. Other areas of trauma may be present. Optimally, the animal should be stabilized before surgery. If the diaphragmatic tear is chronic, it is necessary to be especially careful with anesthesia, because reexpansion pulmonary edema is likely fatal.

LARYNGEAL DISORDERS

See also LARYNGEAL HEMIPLEGIA, p 1458.

Laryngitis, an inflammation of the mucosa or cartilages of the larynx, may result from upper respiratory tract infection or by direct irritation from inhalation of dust, smoke, or irritating gas; foreign bodies; or the trauma of intubation, excess vocalization, or injury from roping or restraint devices (in livestock). Laryngitis may accompany infectious tracheobronchitis and distemper in dogs; infectious rhinotracheitis and calicivirus infection in cats; infectious rhinotracheitis and calf diphtheria in cattle; strangles, herpesvirus 1 infection, viral arteritis, and infectious bronchitis in horses; *Fusobacterium necrophorum* or *Trueperella pyogenes* infections in sheep; and influenza in pigs.

Edema of the mucosa and submucosa is often an integral part of laryngitis and, if severe, the rima glottidis may be obstructed. Edema may also result from allergy, inhalation of irritants, or surgery in the area. Intubation for anesthesia, especially when attempted with inadequate induction or poor technique, is likely to provoke laryngeal edema. Brachycephalic and obese dogs, and dogs with laryngeal paralysis (see p 1420) develop laryngeal edema and laryngitis through severe panting or respiratory effort during excitement or hyperthermia.

In cattle, laryngeal edema has been seen in blackleg, urticaria, serum sickness, and anaphylaxis. In pigs, it may develop as a part of edema disease. In horses, cattle, and sheep, laryngeal edema may lead to arytenoid chondropathy.

Laryngeal chondropathy is a suppurative condition of the cartilage matrix that principally affects the arytenoid cartilages; it is believed to result from microbial infection, often as a sequela of inhalation of irritants or trauma to the area. In herbivores, trauma can occur when administering medications by bolus or drench or by ingestion of rough foodstuffs; in dogs, trauma can occur from sticks or foreign bodies. Laryngeal chondropathy is characterized by necrosis and ulceration of the laryngeal mucosa, over or just caudal to the vocal cords, and abscessation within the arytenoid cartilage. Initially, there is often acute laryngeal inflammation. Later, there is progressive enlargement of the cartilages that commonly results in a fixed upper airway obstruction with stertorous breathing and reduced exercise tolerance. Laryngeal chondropathy is seen in horses, sheep, and cattle, most often young males. There is a distinct breed predisposition in Texel sheep and Belgian Blue cattle. Laryngeal contact ulcers are common in young feedlot cattle and often result in necrotic laryngitis and chondropathy.

Clinical Findings: A cough is the principal sign of laryngitis when edema is slight and the deeper tissues of the larynx are not involved. It is harsh, dry, and short at first, but becomes soft and moist later and may be very painful. It can be induced by pressure on the larynx, exposure to cold or dusty air, swallowing coarse food or cold water, or attempts to administer medicines. Vocal changes may be evident, especially in small animals. Stridor may result from swelling and reduced motion of the arytenoid cartilages in laryngeal chondropathy. Halitosis and difficult, noisy breathing may be evident, and the animal may stand with its head lowered and mouth open. Swallowing is difficult and painful. Systemic signs are usually attributable to the primary disease, as in infectious bovine rhinotracheitis, in which temperatures of 105°F (40.5°C) may occur. Secondary systemic signs due to inappetence and dehydration rapidly become apparent. Death due to asphyxiation may occur, especially if the animal is exerted.

Edema of the larynx may develop within hours. It is characterized by increased inspiratory effort and stridor arising from the larynx. Respiratory rate may slow as the effort of breathing becomes exaggerated. Visible mucous membranes are cyanotic, the pulse rate is increased, and body temperature rises. Horses may sweat profusely. Dogs with obstructions of the conducting airways may show extreme disturbance of thermoregulation in hot weather; marked hyperthermia is not uncommon. Untreated animals with marked obstruction eventually collapse and often have signs of pulmonary edema.

Diagnosis: A tentative diagnosis is based on the clinical signs, auscultation of the laryngeal region, and exacerbation of stridor by palpation of the larynx. Definitive diagnosis requires laryngoscopy. In conscious horses and cattle, this can be achieved with a flexible endoscope passed per nasum; in dogs and cats, anesthesia or analgesia usually is required. The history and signs usually permit rapid identification of the primary disease and the associated laryngeal involvement. Bilateral laryngeal paralysis, laryngeal abscess, pharyngeal trauma and cellulitis, and retropharyngeal abscesses or masses can cause similar signs.

Treatment: In laryngeal obstruction, a tracheotomy tube should be placed immediately; if a tracheotomy is not

possible, airway patency may be established by passage of a pliable tube through the glottis. Corticosteroids should be administered to reduce the obstructive effect of the inflammatory swellings. Concurrent administration of systemic antibiotics is also necessary. In cases in which corticosteroids cannot be used, NSAIDs can be given. Administration of diuretic drugs, eg, furosemide, may be indicated to resolve laryngeal edema and, if present, pulmonary edema. Identification and treatment of the primary disease is essential. Palliative procedures to speed recovery and give comfort include inhalation of humidified air; confinement in a warm, clean environment; feeding of soft or liquid foods; and avoidance of dust. The cough may be suppressed with antitussive preparations, and bacterial infections controlled with antibiotics or sulfonamides. Control of pain with judicious use of an analgesic, especially in cats, allows the animal to eat, and thus speeds recovery. Subtotal arytenoidectomy is an effective remedy for laryngeal chondropathy of horses, although a return to full athletic capacity in competitive horses is uncertain. Tracheolaryngostomies and permanent tracheostomies have been used successfully to salvage cattle and sheep with laryngeal chondropathy but carry significant anesthetic risk. A medical alternative for ruminants is prolonged antibiotic therapy, 14–21 days of parenteral lincomycin (5–10 mg/kg), plus initial, short-acting corticosteroids.

LARYNGEAL PARALYSIS

Laryngeal paralysis is common in dogs and rare in cats. Signs include a dry cough, voice changes, noisy breathing that progresses to marked difficulty in breathing with stress and exertion, stridor, and collapse. Regurgitation and vomiting may occur. Progression of clinical signs is slow, usually taking months to years before respiratory distress is evident. It is a common acquired problem in middle-aged to older, large and giant breeds of dogs, eg, Labrador Retrievers, Irish Setters, and Great Danes. It is seen less often as a hereditary, congenital disease in Bouvier des Flandres, Leonbergers, Siberian Huskies, Bulldogs, and racing sled dogs.

Diagnosis is based on clinical signs; laryngoscopy under light anesthesia is needed for confirmation. Laryngeal movements are absent or paradoxical with respiration. Electromyography shows positive sharp waves, denervation

potentials, and sometimes myotonia. Radiographs are not diagnostic. Denervation atrophy is seen on histologic sections of laryngeal muscles.

Differential diagnoses include myositis, recurrent laryngeal or vagal nerve tumor, inflammation, myasthenia gravis, severe hypothyroidism, trauma, and more widespread generalized neurologic degeneration. Therapy is directed at relieving signs of airway obstruction. Tranquilization and corticosteroids are effective temporarily in mild cases. Severe obstruction may require tracheotomy. Definitive

therapy is surgical and directed at enlarging the glottic opening. Currently recommended techniques include arytenoid cartilage lateralization, ventriculocordectomy and partial arytenoidectomy, castellated laryngofissure, or permanent tracheostomy. Studies have demonstrated that bilateral ventriculocordectomy through a ventral median laryngotomy has had good longterm treatment success for surgical treatment of idiopathic laryngeal paralysis in dogs, and unilateral arytenoid lateralization appeared to be a suitable method to treat laryngeal paralysis in cats.

LUNGWORM INFECTION

(Verminous bronchitis, Verminous pneumonia)

An infection of the lower respiratory tract, usually resulting in bronchitis or pneumonia, can be caused by any of several parasitic nematodes, including *Dictyocaulus viviparus* in cattle, llamas, and alpacas; *D. filaria* in goats, sheep, llamas, and alpacas; *D. eckerti* in deer; *D. arnfieldi* in donkeys and horses; *Protostrongylus rufescens* and *Muellerius capillaris* in sheep and goats; *Metastrongylus apri*, *M. pudendotectus*, and *M. salmi* in pigs; *Ostertus ostertus*, *Crenosoma vulpis*, and *Eucoleus aerophilus* in dogs; and *Aelurostrongylus abstrusus* and *E. aerophilus* in cats. Other lungworm infections occur but are less common.

Species of *Dictyocaulus* belong to the superfamily Trichostrongyloidea and have direct life cycles. *E. aerophilus* belongs to the Trichuroidea and is thought to have a direct life cycle. The others belong to the Metastrongyloidea and, except for *O. ostertus*, have indirect life cycles.

Some nematodes that inhabit the right ventricle and pulmonary circulation, eg, *Angiostrongylus vasorum* and *Dirofilaria immitis*, both found in dogs in certain areas of the world, may be associated with pulmonary disease. Clinical signs relating to a cardiac or a pulmonary syndrome or to a combination of both may occur.

Epidemiology: Diseases caused by the ruminant *Dictyocaulus* spp are of most economic importance. The cattle lungworm

D. viviparus is common in northwest Europe and is the cause of severe outbreaks of "husk" or "hoose" in young (and more recently, older) grazing cattle. The lungworm of goats and sheep, *D. filaria*, is comparatively less pathogenic but does cause losses, especially in Mediterranean countries, although it is also recognized as a pathogen in Australia, Europe, and North America. *D. filaria* and *D. viviparus* are less pathogenic in alpacas and llamas, although severe infections can cause coughing, dyspnea, depression, and loss of condition. *D. arnfieldi* can cause severe coughing in horses and, because patency is unusual in horses (but not in donkeys), differential diagnosis with disease due to other respiratory diseases can be difficult. *M. capillaris* is prevalent worldwide and, although usually nonpathogenic in sheep, can cause severe signs in goats. Other lungworm infections cause sporadic infections in various animal species in many countries.

***Dictyocaulus* spp:** Adult females in the bronchi lay larvated eggs that hatch either in the bronchi (*D. viviparus*, *D. filaria*) or in host feces (*D. arnfieldi*) after being coughed up and swallowed. The infective third-stage larvae can develop on pasture within 5–7 days in warm, moist conditions, but typically in summer in temperate northern climates will require 2–3 wk. Once larvae are infective, transmission depends on their dispersal away from the fecal pats.

Dispersal mechanisms are, primarily, mechanical and include rain or, in the case of *D viviparus* and possibly *D arnfieldi*, by the sporangia of the fungus *Pilobolus*. A proportion of infective larvae survive on pasture throughout the winter until the following year but, in very cold conditions, most become nonviable. The principal source of new infections each year is from infected carrier animals, with overwintered larvae providing a secondary but not unimportant contribution in some countries. In the case of *D arnfieldi*, donkeys are the prime source of pasture contamination for horses. Clinical disease in ruminants usually develops on first exposure to sufficient infective larvae; the severity of disease and stimulation of an immune response is related to the number of larvae ingested. In cattle and sheep, this usually occurs during their first season at pasture; however, an increase in the number of older cattle affected has been reported and is attributed to the efficiency of some prophylactic anthelmintic regimens, which eliminates infection and prevents development of a protective immune response. Because transmission of infection to horses requires infected donkeys (patent infections rarely occur in adult horses but may occur in foals and yearlings), first infections can occur at any age in that species. Once infected, adult ruminants generally become immune to further disease, but a proportion maintain subclinical infections during which they act as a source of further pasture contamination. Occasionally, when previously infected adults or groups that have not been exposed to reinfection for >1 yr, and in which immunity may have waned, are exposed to an overwhelming level of infection, clinical disease may recur. In areas of Europe in which cattle are housed during winter and first grazing season calves turned out in late April or May, the first infections can be seen between mid June and late July, but most severe infections generally occur in previously unexposed calves after development of the second generation of infective larvae on pasture between August and early October.

Other Species: *Metastrongylus* spp in pigs require an earthworm intermediate host; thus, infection is confined to pigs with access to pasture and may become more common in previously uncommon areas as a result of organic farming methods. *M capillaris* and *P rufescens* in sheep and goats require slugs or snails as intermediate hosts, which must be eaten for infection to occur. *C vulpis* is acquired by dogs

through ingestion of an infected terrestrial snail or slug intermediate host. *A abstrusus* is normally acquired by cats after ingestion of a paratenic host such as a bird or rodent that has previously eaten the infected slug or snail intermediate host. Adults of *O osleri* live in nodules in the trachea of dogs, and larvated eggs laid by adults hatch there. Larvae migrate up the bronchial tree and may pass in the feces; however, these are not active, are often dead or degenerating, and are not an important route of transmission. Infection in domestic dogs is mainly through saliva as the dam cleans her pups. *E aerophilus* in dogs likely has a direct cycle, with larvated eggs being ingested with food or water.

Pathogenesis: The pathogenic effect of lungworms depends on their location within the respiratory tract, the number of infective larvae ingested, and the animal's immune state. During the prepatent phase of *D viviparus* infection, the main lesion is blockage of bronchioles by an infiltrate of eosinophils in response to the developing larvae; this results in obstruction of the airways and collapse of alveoli distal to the block. Clinical signs are moderate unless large numbers of larvae are ingested, in which case the animal may die in the prepatent phase with severe interstitial emphysema and pulmonary edema.

In the patent phase, the adults in the segmental and lobar bronchi cause a bronchitis, with eosinophils, plasma cells, and lymphocytes in the bronchial wall; a cellular exudate, frothy mucus, and adult nematodes are found in the lumen. The bronchial irritation causes marked coughing, and the entire reaction leads to increased airway resistance. A major component of the patent stage is development of a chronic, nonsuppurative, eosinophilic, granulomatous pneumonia in response to eggs and first-stage larvae aspirated into alveoli and bronchioles. This is usually in the caudal lobes of the lungs and is severe when widespread; in combination with the bronchitis, death may result. Interstitial emphysema, pulmonary edema, and secondary bacterial infection are complications that increase the likelihood of death. Survivors may suffer considerable weight loss.

If the animal survives until the end of patency (2–3 mo for *D viviparus*), most or even all of the adult worms are expelled, and the cellular exudate resolves over the ensuing 4 wk. Most animals recover unless secondary infection develops in the

damaged lungs during the postpatent phase. In a few animals, clinical signs are exacerbated in the postpatent phase due to development of a diffuse, proliferative alveolitis characterized by hyperplasia of the type II alveolar epithelial cells. The cause is unknown, but it is seen much less often in cattle treated with anthelmintics with a persistent action against *D viviparus* such as the macrocyclic lactones ivermectin, doramectin, eprinomectin, and moxidectin.

D. filaria is similar to *D viviparus*, but interstitial emphysema is not a common complication. Bronchial lesions predominate in *D armfieldi* infections; when an alveolar reaction occurs, as in donkeys or foals, there are lobular areas of overinflation due to intermittent obstruction of small bronchi.

The pathogenic effect of the other lungworms has a similar basis, but frequently such severe clinical signs are not produced, perhaps because of a more restricted localization in the lungs and less severe infections. The patent phase and the associated lesions last >4 mo for some lungworms (*M apri* and *A abstrusus*) but can be >2 yr (*M capillaris*). The lesions in pigs with metastrongylosis are a combination of localized bronchitis and bronchiolitis with overinflation of related alveoli, usually at the tips and midway along the diaphragmatic lobes. Associated with the mass of nematodes in the lumen is hypertrophy and hyperplasia of bronchiolar and alveolar duct smooth muscle with marked mucous cell hyperplasia. Near the end of the patent period (as adult worms are killed), gray-green lymphoid nodules (2–4 mm) are formed; fragments of dead worms may be seen microscopically in these nodules composed of lymphocytes and plasma cells surrounding a central zone of eosinophils.

In *M capillaris* and *P rufescens* infections, chronic, eosinophilic, granulomatous pneumonia seems to predominate; the reaction is in the bronchioles and alveoli that contain the parasites, their eggs, or larvae. They are surrounded by macrophages, giant cells, eosinophils, and other immunoinflammatory cells, which produce gray or beige plaques (1–2 cm) subpleurally in the dorsal border of the caudal lung lobes. Small (1–2 mm), greenish, nodular lesions may also develop. The effect of these lesions in sheep is minor, perhaps because of the predominantly subpleural location. This infection represents the lower end of the pathogenic spectrum for lungworms.

In cats, *A abstrusus* produces nodular areas of granulomatous pneumonia in the caudal lobes that, if sufficiently generalized, can be clinically significant and occasionally fatal; a notable feature is the hypertrophy and hyperplasia of the smooth muscle in the media of pulmonary arteries and arterioles. The nodules of *O ostleri*, found in the mucous membrane of the trachea and large bronchi, can produce extreme airway irritation and persistent coughing. *C vulpis* infections result in chronic bronchitis and bronchiolitis, which leads to chronic coughing. *E aerophilus* infections in dogs are usually well tolerated but may cause chronic tracheitis and bronchitis.

In adult animals not previously exposed to infection, the lesions and pathogenesis are the same as in young animals. However, in adults with some degree of immunity, reexposure to the parasite (eg, husk in adult cattle) can result in different lesions. Despite the immune response, many larvae reach the lungs before they are killed in the terminal bronchioles and alveoli. Larvae not killed in the terminal bronchioles may reach the bronchi and cause a bronchitis characterized by marked eosinophilic infiltration of the bronchial walls and greenish yellow exudate in the lumen comprising eosinophils, other inflammatory cells, and parasitic debris. The reaction associated with this process can lead to severe clinical signs if the nodules are numerous and the eosinophilic bronchitis extensive; this is responsible for the reinfection phenomenon.

Clinical Findings: Signs of lungworm infection range from moderate coughing with slightly increased respiratory rates to severe persistent coughing and respiratory distress and even failure. Reduced weight gains, reduced milk yields, and weight loss accompany many infections in cattle, sheep, and goats. Patent subclinical infections can occur in all species.

The most consistent signs in cattle are tachypnea and coughing. Initially, rapid, shallow breathing is accompanied by a cough that is exacerbated by exercise. Respiratory difficulty may ensue, and heavily infected animals stand with their heads stretched forward and mouths open and drool. The animals become anorectic and rapidly lose condition. Lung sounds are particularly prominent at the bronchial bifurcation. In adult dairy cattle, milk yield drops severely, and abnormal lung sounds are heard over the caudal lobes. The reinfection phenomenon in adult dairy cattle is usually seen in the fall; although

less severe than in initial infections, the signs are widespread coughing and tachypnea and a marked drop in milk yield.

The signs in llamas, alpacas, sheep, and goats infected with *D. filaria* are similar to those in cattle. Pulmonary signs usually are not associated with *M. capillaris* or *P. rufescens* in sheep, but the former can affect goats similarly to *D. filaria*. *D. arnfieldi* is associated with coughing, tachypnea, and unthriftiness in older horses but with few if any signs in foals or donkeys.

The main clinical sign of metastrongylosis in pigs is a persistent cough that may become paroxysmal.

Coughing and dyspnea occur with *A. abstrusus* infections in cats and *O. osleri* or *C. vulpis* infections in dogs. Fatalities are relatively uncommon with these lungworms, although they do occur in kittens.

Diagnosis: Diagnosis is based on clinical signs, epidemiology, presence of first-stage larvae in feces, and necropsy of animals in the same herd or flock. Bronchoscopy and radiography may be helpful. Larvae are not found in the feces of animals in the prepatent or postpatent phases and usually not in the reinfection phenomenon (*D. viviparus*). ELISA tests are available in some countries. The test is mainly of use in detecting cattle that have not been exposed, rather than as a differential diagnostic tool in acute respiratory disease. In the early stages of an outbreak, larvae may be few in number. First-stage larvae or larvated eggs can be recovered using most fecal flotation techniques with the appropriate salt solutions; however, larvae will crenate if allowed to sit for a long time on the slide before examination, making identification difficult. Bronchial lavage can reveal *D. arnfieldi* infections in horses. A convenient method to recover larvae is a modification of the Baermann technique, in which large fecal samples (25–30 g) are wrapped in tissue paper or cheese cloth and suspended or placed in water contained in a beaker. The water at the bottom of the beaker is examined for larvae after 4 hr; in heavy infections, larvae may be present within 30 min.

In domestic pets, detection of first-stage larvae in the feces, either on flotation or with the Baermann technique, is still the diagnostic technique of choice. However, in dogs, cats, and horses, because of the relative infrequency of infection in many areas, lungworms may be considered only after failure of

antibiotic therapy to ameliorate the condition. Adults of *Dictyocaulus* spp and *M. apri* are readily visible in the bronchi during the patent phases of infection. However, examination of smears from bronchial mucus or histologic sections from lesions may be necessary to confirm the diagnosis during other stages of lungworm infection (and also for other lungworms).

Bronchoscopy can be used to detect nodules of *O. osleri* or to collect tracheal washings (dogs and horses) to examine for eggs, larvae, and eosinophils.

Necropsy should include examination of the trachea, particularly at the bifurcation, for *O. osleri* and the lesions they induce.

Treatment: Several drugs are useful to treat lungworms (see TABLE 1). The benzimidazoles (fenbendazole, oxfendazole, and albendazole) and macrocyclic lactones (ivermectin, doramectin, eprinomectin, and moxidectin) are frequently used in cattle and are effective against all stages of *D. viviparus*. These drugs are also effective against lungworms in sheep, horses, and pigs. Levamisole is used in cattle, sheep, and goats, but treatment may need to be repeated 2 wk later because it is less effective against larvae during the early stages. Topical formulations containing moxidectin, selamectin, or emodepside and oral fenbendazole have been used successfully in cats for *A. abstrusus*. *O. osleri* in dogs is a problem, but there is evidence that fenbendazole and ivermectin are effective if treatment is prolonged (fenbendazole). Injectable doramectin along with removal of as many nodules as possible is the current treatment of choice. *E. aerophilus* in dogs and cats is similarly difficult to treat, but success has been reported with ivermectin, fenbendazole, or selamectin.

Animals at pasture should be moved off infected pasture, and supportive therapy may be needed for complications that can arise in all species.

Control: Lungworm infections in herds or flocks are controlled primarily by vaccination or anthelmintics. Oral vaccines are available in Europe for *D. viviparus* (northeastern areas) and *D. filaria* (southeast). Two doses of irradiated infective larvae are given 4 wk apart, with the second dose given at least 2 wk before the start of grazing or exposure to probable infection. Used properly, they prevent clinical disease,

TABLE 1 RECOMMENDED TREATMENTS FOR LUNGWORMS

Parasite	Host	Treatment ^a
<i>Dictyocaulus viviparus</i>	Cattle	Ivermectin, doramectin, moxidectin, eprinomectin, fenbendazole, albendazole, levamisole
<i>D. filaria</i>	Sheep, goat	Ivermectin, doramectin, moxidectin, eprinomectin, fenbendazole, albendazole, levamisole
<i>D. arnfieldi</i>	Horse, donkey	Ivermectin, moxidectin
<i>Metastrongylus</i> spp	Pig	Ivermectin, doramectin, moxidectin, fenbendazole, levamisole
<i>Aelurostrongylus abstrusus</i>	Cat	Fenbendazole, emodepside, moxidectin, selamectin
<i>Ostlerus ostleri</i>	Dog	Fenbendazole, ivermectin, doramectin
<i>Eucoleus aerophilus</i>	Dog, cat	Fenbendazole (dog), selamectin (cat) ^b
<i>Crenosoma vulpis</i>	Dog	Febantel, fenbendazole, milbemycin oxime, moxidectin

^a In severe cases, NSAIDs may also be helpful.

^b Anecdotal evidence for efficacy but no published evidence or label recommendations.

but some vaccinated animals may become mildly infected to the extent that larvae are excreted and perpetuate further infection.

Anthelmintic prophylaxis has become feasible with the advent of anthelmintics with prolonged activity (eg, ivermectin, doramectin, moxidectin, eprinomectin). With persistent anthelmintics, two or three treatments during the grazing season, the timing of which depends on local grazing practice and epidemiology, are effective and may, by disrupting developing infections, stimulate

immunity to the parasite. The use of multiple treatments may delay immunity to *D. viviparus* until the animal is adult, when infection (albeit usually less severe) can occur. However, these methods have become popular in that GI parasites are controlled simultaneously.

Other more sporadic infections can be controlled more easily by management, eg, avoidance of grazing horses with donkeys, indoor husbandry of pigs, and by not mixing sheep and goats on the same grazing.

MYCOTIC PNEUMONIA

Fungal infection of the lung may result in an acute to chronic active, pyogranulomatous pneumonia.

Etiology: *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*, *Pneumocystis jiroveci*, *Aspergillus* spp, *Candida* spp, and other less common fungi have been identified as causative

agents of mycotic pneumonia in immunocompromised hosts (see also FUNGAL INFECTIONS, p 632). Infection is typically caused by inhalation of spores, which can lead to hemolymphatic dissemination. Pulmonary tissues and secretions are an excellent environment for these organisms. Aspergillosis is most commonly associated with sinonasal infection in dogs or sino-orbital infection in cats,

with systemic infection being quite rare and seen only in immunocompromised individuals. Cryptococcosis most commonly affects the nasal cavity in cats, with CNS infection less commonly encountered in dogs and cats. The source of most fungal infections is believed to be soil-related rather than horizontal transmission.

Clinical Findings: Mycotic pneumonia is more commonly seen in small animals than in large. The most common course of disease is chronic. A short, productive cough is often present. A thick, mucoid to mucopurulent nasal discharge may be present. As the disease progresses, dyspnea, emaciation, and generalized weakness become increasingly evident. Respiration may become abdominal, with crackles on auscultation. Generalized lymphadenopathy is common in dogs. Multiple cutaneous and subcutaneous nodules with draining tracts may be seen with blastomycosis in dogs. Blastomycosis is often associated with emaciation and diarrhea in dogs, with skin lesions common in cats. Coccidiomycosis is often associated with severe bone pain due to osteomyelitis in dogs, with skin lesions common in cats. Uveitis or granulomatous chorioretinitis may accompany dimorphic fungal infections. (*See also* FUNGAL INFECTIONS, p 632.)

Lesions: Multifocal to coalescing lesions of granulomatous to pyogranulomatous inflammation are present in the lungs or other affected organs. Abscess formation and cavitation may be seen in conjunction with yellow or gray areas of necrosis. Causative organisms are present within macrophages or areas of intense inflammation.

Diagnosis: Thoracic radiographs often disclose a diffuse pattern with tracheobronchial lymphadenopathy in dogs or large focal pulmonary granulomas in cats. If bone pain is present, skeletal radiography shows osteolysis with periosteal proliferation and soft-tissue swelling at infected sites. Abdominal radiography may reveal granulomas or lymphadenopathy. The clinical diagnosis can be confirmed with impression smears of cutaneous draining tracts, fine-needle aspirate of the lung, lymph node aspirates, or CSF tap (cryptococcosis). Special stains can be used to highlight the organisms.

Treatment: Treatment of mycotic pneumonia is often lengthy. Drugs of choice include itraconazole, fluconazole (cryptococcosis), lipid-complexed amphotericin B, and terbinafine (aspergillosis). Newer generation azole antifungals such as voriconazole or posaconazole are more effective for resistant infections or systemic aspergillosis.

PHARYNGITIS

Pharyngitis is an inflammatory condition of the walls of the oro- or nasopharynx. Pharyngitis may develop secondary to viral or bacterial infections of the upper respiratory tract, eg, strangles in horses and distemper in dogs.

In most species, a common pharynx is present at times other than deglutition. The unique caudal pharyngeal-laryngeal anatomy of horses shows complete separation of the pharynx into two components, the nasopharynx and the oropharynx. (*See also* PHARYNGEAL LYMPHOID HYPERPLASIA, p 1459.)

Clinical Findings: Animals affected with pharyngitis have a normal desire to eat and

drink but may have difficulty swallowing and appear dysphagic. Animals with secondary peripharyngeal cellulitis and abscessation may be acutely dyspneic secondary to pharyngeal obstruction. For example, foals affected with suppurative pharyngitis secondary to abscessation of the retropharyngeal lymph nodes can become acutely dyspneic and require an emergency tracheotomy.

Diagnosis: The diagnosis of pharyngitis can be made with a complete physical examination, radiography of the skull, endoscopic evaluation of the pharynx, and microbial cultures of draining

abscesses or nasopharyngeal swabs for viral isolation. In small animals, oral pain and resistance to having the mouth opened may indicate retropharyngeal abscessation and the presence of a penetrating foreign body or oral or tonsillar neoplasia. Abnormal pharyngeal tissue should be biopsied and submitted for histopathology to exclude pharyngeal neoplasia. In small animals, oral examination and/or endoscopic examination is the best diagnostic tool for pharyngitis. In large animals, the diagnosis of pharyngitis is easily made by endoscopic examination of the upper respiratory tract.

Treatment: Bacterial pharyngitis should be treated with systemic antimicrobials based on microbial culture and sensitivity testing. Abscesses should be drained and lavaged when appropriate. Viral-induced pharyngitis should be managed with antimicrobials to prevent secondary bacterial infections. Animals affected with either bacterial or viral pharyngitis should be treated with NSAIDs. Pharyngitis secondary to foreign bodies should be resolved with removal of the offending object and effective surgical drainage accompanied by excision of necrotic tissue.

Racehorses affected by pharyngeal lymphoid hyperplasia can be treated with topical and systemic anti-inflammatory agents such as flunixin meglumine, phenylbutazone, or dexamethasone. A commonly used topical anti-inflammatory treatment includes prednisolone, DMSO, glycerin, and nitrofurazone. Large pharyngeal masses can also be treated with contact diode laser photoablation. Some veterinarians have also found hyperimmunization helpful in managing pharyngeal lymphoid hyperplasia.

Calicivirus infections in cats may cause mild, moderate, or severe ulceration of the oropharyngeal mucosa. Although specific antiviral therapies are not available, affected cats should be treated with systemic antimicrobials to prevent secondary bacterial infection. Animals that cannot maintain their own hydration because of severe mucosal ulceration may require nutritional and electrolyte supplementation either intravenously or by extraoral alimentation.

PHARYNGEAL TRAUMA

Pharyngeal trauma in ruminants is not uncommon secondary to iatrogenic

Stylohyoid fracture in a horse. Courtesy of Dr. Sameeh M. Abutarbush.

causes, such as incorrect passage of balling guns or attempts to pass probangs per os. Affected cattle develop severe swelling of the head and proximal neck secondary to diffuse cellulitis caused by penetration of the pharyngeal mucosa. Feed frequently becomes impacted in these areas and can lead to acute dyspnea. Management of pharyngeal trauma in ruminants should include the placement of a temporary rumen fistula to provide extraoral alimentation while the pharyngeal defect heals. Treatment should also include systemic antimicrobials and anti-inflammatory agents. Some affected animals may also require surgical drainage of accumulated feed and abscessation secondary to the foreign material.

In small animals, oropharyngeal foreign bodies are quite common in dogs but less so in cats. However, cats are prone to ingestion of linear foreign bodies, which may become entangled with the tongue and can be identified with a careful oral examination under sedation or general anesthesia. Penetrating foreign bodies include pins, needles, and pieces of stick or bone fragments. Small animals suspected to have oropharyngeal foreign bodies should be evaluated with an oral examination while sedated or anesthetized and with radiographs or ultrasound to identify all foreign material present. Once identified, pharyngeal foreign bodies may be removed directly via the oral cavity or approached externally.

PULMONARY EMPHYSEMA

Two major forms of pulmonary emphysema are generally recognized. **Alveolar emphysema** is abnormal permanent enlargement of air spaces distal to the terminal bronchiole and destruction of alveolar septal walls without apparent fibrosis. **Interstitial emphysema** is the presence of air within the supporting connective tissue stroma of the lung (interlobular, subpleural, mediastinal, subcutaneous).

Epidemiology and Pathogenesis:

Emphysema affects ~10% of people with chronic obstructive pulmonary disease; the main risk factors are tobacco smoke exposure and α_1 -antitrypsin deficiency. In animals, it typically occurs secondary to a primary obstructive pulmonary disease process. While the pathogenesis of pulmonary emphysema is not fully understood, at least three mechanisms have been suggested: 1) an imbalance between protease secreted by neutrophils and macrophages, and antiprotease activity results in destruction of alveolar walls and interstitial matrix; 2) inappropriate maintenance of lung structure and repair follows injury; and 3) the condition develops secondary to obstruction of airways on expiration due to chronic bronchitis/bronchiolitis or congenital abnormality of the airway wall. This creates a "check valve" lesion, in which air is able to enter alveoli on inspiration or through collateral ventilation but is unable to leave freely and causes air trapping.

Recurrent airway obstruction, or "heaves" in horses (see p 1455), is associated with chronic bronchitis and bronchiolitis, resulting in alveolar hyperinflation by air trapping. The condition is partially reversible with bronchodilators; however, a small subset of horses develop alveolar emphysema presumably from chronic overdistention of alveolar walls and protease/antiprotease imbalance associated with pulmonary inflammation. Congenital lobar emphysema of dogs (as seen in the Pekingese breed) occurs secondary to aplasia or hypoplasia of bronchiolar cartilage that collapses during expiration, leading to air trapping. Because of well-developed interlobular septa and lack of collateral ventilation, cattle are particularly

susceptible to interstitial emphysema. Pulmonary diseases associated with airway obstruction and dyspnea, such as bovine respiratory syncytial virus infection, acute respiratory disease syndromes, such as acute pulmonary edema and emphysema (see p 1439), and moldy sweet potato toxicity (see p 1442) are commonly associated with interstitial emphysema. Severe interstitial emphysema can cause large gas bullae in all parts of the lung and subcutaneous emphysema as air dissects along fascial planes from the lungs through the mediastinum and thoracic inlet to the subcutis of the back.

Clinical Findings and Diagnosis:

Clinical signs depend on the primary disease process. Often, affected animals present with labored breathing, and auscultation reveals abnormal breath sounds such as wheezes and crackles due to airway disease. The area of thoracic auscultation is typically enlarged due to lung hyperinflation. At necropsy, the lungs do not collapse and stay overinflated. Histology is the only method to differentiate lung overinflation secondary to pulmonary emphysema from air trapping due to airway obstruction from chronic bronchiolitis or bronchitis. Air bubbles (bullae) of various sizes may be seen in the subpleural space and interstitium, as well as around the kidneys and pericardial sac in cattle with emphysema. Pulmonary emphysema affects a small percentage of horses with recurrent airway obstruction (~12%). Lesions may develop as subpleural bullae or emphysema localized to a lobe or diffused lesions.

Minor degrees of emphysema may precede death if there was a prolonged struggle or exaggerated respiration. These agonal changes should be differentiated from antemortem lesions.

Treatment: Emphysema is an irreversible lung lesion; however, therapy directed toward the primary disease process may result in significant improvement of clinical signs, especially by targeting airway obstruction with administration of bronchodilator and anti-inflammatory drugs.

RESPIRATORY DISEASES OF CATTLE

Respiratory disease is among the most economically important diseases of cattle in production on a worldwide basis.

ALLERGIC RHINITIS AND ENZOOTIC NASAL GRANULOMA

Allergic rhinitis is an uncommon disease of cattle that, when chronic, may lead to granuloma formation. The etiology is an allergic reaction to pollen or fungal spores. Signs are seasonal and occur under warm, moist conditions; they include rhinorrhea, sneezing, and a sudden onset of dyspnea. In the chronic stage, multiple granulomas may form on the mucosal surface of the nasal cavity. Cytologic examination of nasal discharges may reveal eosinophils. Treatment should focus on removing the allergen or removing the animal from the allergen. Treatment with corticosteroids to block the hypersensitivity reaction is a consideration.

SINUSITIS

Etiology: Sinusitis in cattle typically involves the frontal or maxillary sinus. Frontal sinusitis is usually associated with dehorning, and maxillary sinusitis with infected teeth. Numerous bacteria have been isolated from sinusitis infections in cattle.

Clinical Findings: Frontal sinusitis may occur immediately after dehorning while the site is still open or months later after the dehorning site has healed. The condition is most often unilateral. Signs may include anorexia, pyrexia, unilateral or bilateral nasal discharge, changes in air flow through the nasal passages, and foul breath. Head carriage may be abnormal. In longstanding cases of frontal sinusitis, there may be distortion of the frontal bone, exophthalmos, and neurologic signs.

Diagnosis: Diagnosis can usually be made on the basis of clinical signs. Percussion may reveal a dull sound over the affected sinus. Radiographs may reveal fluid in the sinus, the presence of dental disease, or

bone lysis. Cytology of aspirated material from the affected sinus may reveal purulent material.

Treatment: Sinusitis is treated by draining the affected sinus. Trephine sites should be selected carefully, using appropriate anatomic landmarks. If an infected tooth is the cause of maxillary sinusitis, the tooth can be repelled through a sinusotomy site created with a trephine. Once drainage has been established, the sinus can be lavaged daily with antiseptic solutions. Treatment with parenteral antibiotics is indicated if systemic signs are present. NSAIDs can be given for pain relief, if needed. The prognosis is guarded.

Control: The best control method is to dehorn calves at a young age using a closed dehorning technique. If this is not possible, close attention should be paid to disinfection of surgical instruments between animals, dust control, and fly control.

NECROTIC LARYNGITIS

(Calf diphtheria, Laryngeal necrobacillosis)

Fusobacterium necrophorum, a gram-negative, nonsporeforming anaerobe, is a normal inhabitant of the alimentary, respiratory, and genital tract of animals. The organism is an opportunistic pathogen that causes several necrotic conditions in animals (ie, necrobacillosis), including necrotic laryngitis.

Necrotic laryngitis is an acute or chronic *F necrophorum* infection of the laryngeal mucosa and cartilage of young cattle, characterized by fever, cough, inspiratory dyspnea, and stridor. It occurs primarily in feedlot cattle 3–18 mo of age; however, cases have been documented in calves as young as 5 wk and in cattle as old as 24 mo. Cases are seen worldwide and year round but appear to be more prevalent in fall and winter.

Etiology: Predisposing factors are not fully understood. *F necrophorum*, commonly isolated from laryngeal lesions of affected cattle, is unable to penetrate intact mucous membranes. Laryngeal contact ulcers, a common finding in slaughtered cattle, are thought to provide a portal of entry for *F necrophorum*.

Transmission, Epidemiology, and Pathogenesis:

Necrotic laryngitis is most common where cattle are closely confined under unsanitary conditions or in feedlots. The prevalence in feedlot calves is estimated to be 1%-2%. Most cases are sporadic and occur year round, but disease peaks in fall and winter. Mixed upper respiratory tract infections (caused by infectious bovine rhinotracheitis virus and parainfluenza-3 virus; *Mycoplasma* spp; and bacteria, including *Pasteurella* and *Haemophilus*), and the coughing and swallowing associated with these infections, may predispose feedlot cattle to develop laryngeal contact ulcers. These ulcers on the vocal processes and medial angles of arytenoid cartilages are thought to provide a portal of entry for *F necrophorum*.

F necrophorum causes inflammation, necrosis, and edema in the laryngeal mucosa, resulting in variable narrowing of the rima glottidis and inspiratory dyspnea and stridor. If infection extends into the laryngeal cartilage, laryngeal chondritis develops, which may lead to a chronically deformed larynx. Pharyngeal invasion by the organism causes discomfort characterized by painful swallowing motions. Systemic signs of illness have been attributed to the exotoxin produced by *F necrophorum*.

Clinical Findings: Initially, a moist, painful cough is noticed. Severe inspiratory dyspnea, characterized by open-mouth breathing with the head and neck extended, and loud inspiratory stridor are common findings. Ptyalism; frequent, painful swallowing motions; bilateral, purulent nasal discharge; and a fetid odor to the breath may also be present. Systemic signs may include fever (106°F [41.1°C]), anorexia, depression, and hyperemia of the mucous membranes. Untreated calves die in 2-7 days from toxemia and upper airway obstruction. Longterm sequelae include aspiration pneumonia and permanent distortion of the larynx, resulting in a chronic harsh cough and inspiratory dyspnea.

Lesions: Lesions are typically located over the vocal processes and medial angles of arytenoid cartilages. Acute lesions are characterized by edema and hyperemia surrounding a necrotic ulcer in the laryngeal mucosa; lesions may spread along the vocal folds and processes to involve the cricoarytenoid dorsalis muscle. In chronic cases, lesions consist of necrotic

cartilage associated with a draining tract surrounded by granulation tissue.

Diagnosis: Clinical signs are usually sufficient to establish a diagnosis. However, because numerous other conditions can cause signs of upper airway obstruction, the larynx should be visually inspected to confirm a diagnosis. This can be accomplished by means of an orally inserted speculum, laryngoscopy, endoscopy, or radiography, but care must be exercised to avoid further respiratory embarrassment. A tracheostomy should be performed before laryngoscopic or endoscopic examination in cattle with severe inspiratory dyspnea. Differential diagnoses include pharyngeal trauma; severe viral laryngitis (eg, infectious bovine rhinotracheitis); actinobacillosis; and laryngeal edema, abscesses, trauma, paralysis, or tumors.

Treatment and Control: Oxytetracycline (11 mg/kg, IV or SC, bid, or 20 mg/kg of long-acting tetracycline, SC, every 72 hr) or procaine penicillin (22,000 U/kg, IM, bid) are the antimicrobials of choice. NSAIDs (aspirin, 100 mg/kg, PO, bid; flunixin, 1.1-2.2 mg/kg, IV, once daily or divided bid; or ketoprofen, 3 mg/kg/day, IM or IV, for up to 3 days) are used to decrease the fever and laryngeal inflammation and edema. A single dose of dexamethasone (0.2-0.5 mg/kg, IV or IM) may be used to decrease laryngeal edema in animals with severe respiratory distress. A tracheostomy is indicated in cattle with severe inspiratory dyspnea. Good nursing care should be provided. Intravenous fluids may be required in dehydrated animals. The prognosis is good for early cases treated aggressively; chronic cases require surgery under general anesthesia to remove necrotic or granulation tissue and to drain laryngeal abscesses. A 60% success rate has been reported for surgical intervention in advanced cases.

There are no specific control measures for necrotic laryngitis; however, the proposed pathogenesis suggests that control measures for common respiratory pathogens may be beneficial.

TRACHEAL EDEMA SYNDROME OF FEEDER CATTLE

Tracheal edema syndrome is characterized by extensive edema of the mucosa and submucosa in the dorsal membrane of the lower trachea. The etiology is unknown. Proposed causes include respiratory viruses

and bacteria, trauma to the trachea from feed bunks, passive congestion and edema from excessive fat accumulation in the thoracic inlet, hypersensitivity reactions, and mycotoxins.

The condition occurs in heavy feeder cattle in the later two-thirds of the feeding period throughout North America but may be most severe in the summer in southern plains (USA) feedlots. Onset is sudden and appears to be associated with an increase in respirations stimulated by hot weather or exercise. The initial signs are a loud inspiratory noise (stridor) and the onset of dyspnea. Forced movement causes the respiratory distress to worsen. The cattle become cyanotic and typically collapse and die of asphyxiation in <24 hr. The disease is usually very sporadic, with small numbers of animals in the population affected.

In the acute form, necropsy lesions include edematous and/or hemorrhagic thickening of the submucosa and mucosa of the dorsal trachea extending from the midcervical area to the thoracic inlet. There is extensive hemorrhage in the trachea but no lung lesions. In the chronic form, lesions consist of hyperemia of the caudal third of the trachea with mucopurulent exudate in the trachea. In fatal cases, the lesion becomes completely obstructive.

Movement and handling of affected cattle should be limited. Antibiotics and corticosteroids are recommended for the acute form, although the efficacy of treatment is not reported. Tracheostomy may be required in severe cases. Providing shade and cooling with fans or water sprays is recommended. Animals that recover are prone to relapse and should be sent to slaughter.

BOVINE RESPIRATORY DISEASE COMPLEX

Bovine respiratory disease (BRD) has a multifactorial etiology and develops as a result of complex interactions between environmental factors, host factors, and pathogens. Environmental factors (eg, weaning, transport, commingling, crowding, inclement weather, dust, and inadequate ventilation) serve as stressors that adversely affect the immune and nonimmune defense mechanisms of the host. In addition, certain environmental factors (eg, crowding and inadequate ventilation) can enhance the transmission of infectious agents among animals. Many infectious agents have been

associated with BRD. An initial pathogen (eg, a virus) may alter the animal's defense mechanisms, allowing colonization of the lower respiratory tract by bacteria.

ENZOOTIC PNEUMONIA OF CALVES AND SHIPPING FEVER PNEUMONIA

Enzootic pneumonia and shipping fever pneumonia share many similarities in their respective etiologies and pathogeneses and in general measures for control and prevention.

Enzootic Pneumonia of Calves

(Dairy calf pneumonia, Summer pneumonia of beef calves)

Enzootic pneumonia of calves refers to infectious respiratory disease in calves. The term "viral pneumonia of calves" is sometimes used but is not preferred based on the current understanding of etiology and pathogenesis. Enzootic pneumonia is primarily a problem in calves <6 mo old with peak occurrence from 2–10 wk, but it may be seen in calves up to 1 yr of age. It is more common in dairy than in beef calves and is a common problem in veal calves. It is also more common in housed dairy calves than in those raised outside in hutches. Peak incidence of disease may coincide with decline of passively acquired immunity. Morbidity rates may approach 100%; case fatality rates vary but can reach 20%.

Etiology: The etiology is similar to that for BRD complex in general (see p 1431). The pathogenesis involves environmental and management stressors and possibly an initial respiratory viral infection followed by a secondary bacterial infection of the lower respiratory tract. Stress results from environmental and management factors, including inadequate ventilation, mixing by adding calves to an established group, crowding, and nutritional factors such as poor-quality milk replacers. Partial or complete failure of passive transfer of maternal antibodies is an important host factor related to development of disease. Any of several viruses may be involved, and a variety of bacteria may be isolated from affected calves. Mycoplasmal and bacterial agents, including *Pasteurella multocida*, *Mannheimia haemolytica*, and *Mycoplasma bovis*, represent the most frequently isolated pathogenic organisms. The individual viral and

bacterial etiologies, clinical signs, lesions, and treatment are discussed under VIRAL RESPIRATORY TRACT INFECTIONS, below, and BACTERIAL PNEUMONIA, p 1436.

Control and Prevention: When calves of varying ages are placed in communal pens, control of enzootic pneumonia is difficult. The severity of the pneumonia may be decreased by improved husbandry, proper housing, adequate ventilation, and good nursing care. Prevention begins with vaccinating the cows against specific respiratory viruses and bacteria 3–4 wk prepartum to improve the quality of colostral antibodies. Calves should receive good-quality colostrum at 8%–10% of body wt in the first 6 hr after birth. Newborn dairy calves should be housed individually in hutches or stalls and fed whole milk or a high-quality milk replacer with a fiber content of <0.25% until 8–12 wk old. The use of calf hutches in dairy herds is the preferred standard for calf housing and has been shown to significantly improve calf respiratory health. However, delivering milk to a large number of hutches in cold weather presents a significant challenge. Single calf housing in naturally ventilated calf barns is the next best alternative. Calves should be vaccinated against respiratory viruses 3–4 wk before the first grouping, although in some situations, the presence of passive immunity may interfere with an active immune response. Calves should be of similar age when assembled into groups, and a group should be limited to ≤10. As calves mature, groups can become larger as the size of the herd, facilities, and available labor dictate. An “all in/all out” management style should be practiced when establishing and terminating a group. Newborn beef calves and their dams should be moved from concentrated calving areas as soon as the calf is nursing well and strong enough to travel. The use of screening systems such as the Calf Respiratory Scoring Chart (University of Wisconsin) may serve as an objective tool to evaluate calves for treatment.

Shipping Fever Pneumonia

Shipping fever pneumonia, or undifferentiated fever, is a respiratory disease of cattle of multifactorial etiology with *Mannheimia haemolytica* and, less commonly, *Pasteurella multocida* or *Histophilus somni* (see p 754) being the important bacterial agents involved. Shipping fever pneumonia is associated with the assembly

into feedlots of large groups of calves from diverse geographic, nutritional, and genetic backgrounds. Morbidity in feeder calves often peaks within 7–10 days after assembly in a feedlot. Morbidity can approach 35%–50%, and case fatality is 5%–10%; however, the level of morbidity and mortality strongly depends on the array of risk factors present in the cattle being fed.

Etiology: The pathogenesis of shipping fever pneumonia involves stress factors, with or without viral infection, interacting to suppress host defense mechanisms, which allows the proliferation of commensal bacteria in the upper respiratory tract. Subsequently, these bacteria colonize the lower respiratory tract and cause a bronchopneumonia with a cranioventral distribution in the lung. Multiple stress factors are believed to contribute to suppression of host defense mechanisms. Weaning is a significant stressor, and the incidence of this disease is highest in recently weaned calves. Transportation over long distances serves as a stressor; it may be associated with exhaustion, starvation, dehydration, chilling and overheating depending on weather conditions, and exposure to vehicle exhaust fumes. Additional stressors include passage through auction markets; commingling, processing, and surgical procedures on arrival at the feedlot; dusty environmental conditions; and nutritional stress associated with a change to high-energy rations in the feedlot. The individual viral and bacterial etiologies, clinical signs, lesions, and treatment are discussed under VIRAL RESPIRATORY TRACT INFECTIONS, below, and BACTERIAL PNEUMONIA, p 1436.

Control and Prevention: Prevention of shipping fever pneumonia should focus on reducing the stressors that contribute to development of the disease. Cattle should be assembled rapidly into groups, and new animals should not be introduced to established groups. Mixing of cattle from different sources should be avoided if possible; however, in the North American beef industry, this risk factor is almost unavoidable for large intensive feedlots. Transport time should be minimized, and rest periods, with access to feed and water, should be provided during prolonged transport. Calves should ideally be weaned 2–3 wk before shipment, and surgical procedures should be performed in advance of transport; however, the availability of these “preconditioned” calves is quite limited. Cattle should be processed within 48 hr

after arrival at the feedlot. Adaptation to high-energy rations should be gradual, because acidosis, indigestion, and anorexia may inhibit the immune response. Vitamin and mineral deficiencies should be corrected. Dust control measures should be used.

Metaphylaxis with long-acting antibiotics such as oxytetracycline, tilmicosin, florfenicol, gamithromycin, tildipirosin, or tulathromycin has been widely adopted as a control measure given "on arrival" to cattle at high risk of developing shipping fever pneumonia. Metaphylaxis on arrival has been shown to significantly reduce morbidity and improve rate of gain and, in some cases, reduce mortality. Mass medication in feed or water is of limited value because sick animals do not eat or drink enough to achieve inhibitory blood levels of the antibiotic, and many of these oral antibiotics are poorly absorbed in ruminants.

On arrival, processing usually involves administration of modified-live vaccines for viral antigens and for bacterial components of shipping fever pneumonia. Because most cases of pneumonia occur during the first 2 wk after arrival, these on-arrival vaccines may not have adequate time to stimulate immunity. When possible, vaccinations for the viral and bacterial components of shipping fever pneumonia should be given 2–3 wk before transport or earlier and can be repeated on entry to the feedlot.

VIRAL RESPIRATORY TRACT INFECTIONS

Parainfluenza-3 Virus

Etiology: Parainfluenza-3 virus (PI-3) is an RNA virus classified in the Paramyxoviridae family. Infections caused by PI-3 are common in cattle. Although PI-3 is capable of causing disease, it is usually associated with mild to subclinical infections. The most important role of PI-3 is to serve as an initiator that can lead to development of secondary bacterial pneumonia.

Clinical Findings and Lesions: Clinical signs include pyrexia, cough, serous nasal and lacrimal discharge, increased respiratory rate, and increased breath sounds. The severity of signs worsens with the onset of bacterial pneumonia. Fatalities from uncomplicated PI-3 pneumonia are rare. Lesions include cranioventral lung consolidation, bronchiolitis, and alveolitis with marked congestion and hemorrhage. Inclusion bodies may be identified. Most

fatal cases have a concurrent bacterial bronchopneumonia.

Diagnosis: Diagnostic procedures for PI-3 are similar to those for BOVINE RESPIRATORY SYNCYTIAL VIRUS, *see below*.

Treatment and Prevention: Treatment focuses on the antimicrobial therapy directed toward bacterial pneumonia (*see p 1436*). NSAIDs are also a therapeutic consideration.

PI-3 vaccines are available and are almost always combined with bovine herpesvirus 1 (infectious bovine rhinotracheitis). Modified-live and inactivated vaccines are available for IM administration. Vaccines containing temperature-sensitive mutants for intranasal administration are also available.

Bovine Respiratory Syncytial Virus

Etiology: Bovine respiratory syncytial virus (BRSV) is an RNA virus classified as a pneumovirus in the Paramyxoviridae family. This virus was named for its characteristic cytopathic effect—the formation of syncytial cells. In addition to cattle, sheep and goats can also be infected by respiratory syncytial viruses. Human respiratory syncytial virus (HRSV) is an important respiratory pathogen in infants and young children. Antigenic subtypes are known to exist for HRSV, and preliminary evidence suggests there may be antigenic subtypes of BRSV. BRSV is distributed worldwide, and the virus is indigenous in the cattle population.

BRSV infections associated with respiratory disease occur predominantly in young beef and dairy cattle. BRSV can be considered as a primary BRD pathogen and is also a component of the bovine respiratory disease complex. Passively derived immunity does not appear to prevent BRSV infections but reduces the severity of disease. Initial exposures to the virus are associated with severe respiratory disease; subsequent exposures result in mild to subclinical disease. BRSV is an important virus in the bovine respiratory disease complex because of its frequency of occurrence, predilection for the lower respiratory tract, and ability to predispose the respiratory tract to secondary bacterial infection. In outbreaks, morbidity tends to be high, and the case fatality rate can be 0–20%.

Clinical Findings and Lesions: Fever (104°–108°F [40°–42°C]), depression, decreased feed intake, increased respiratory rate, cough, and nasal and

lacrimal discharge are common. Dyspnea, possibly with open-mouthed breathing, may become pronounced in the later stages of the disease. Subcutaneous emphysema may occur. Secondary bacterial pneumonia is a frequent occurrence. A biphasic disease pattern has been described but is not consistent.

Gross lesions include a diffuse interstitial pneumonia with subpleural and interstitial emphysema along with interstitial edema. These lesions are similar to and must be differentiated from other causes of interstitial pneumonia (*see also* p 1439). Bronchopneumonia of bacterial origin is usually present. Histologic examination reveals syncytial cells in bronchiolar epithelium and lung parenchyma, intracytoplasmic inclusion bodies, proliferation and/or degeneration of bronchiolar epithelium, alveolar epithelialization, edema, and hyaline membrane formation.

Diagnosis: A diagnosis of BRSV requires laboratory confirmation. BRSV is a difficult virus to detect, although chances of isolation may improve when sampling animals in the incubation or acute phases of infection. Although virus isolation is difficult, PCR is a useful and rapid method commonly used to detect the antigen.

Other procedures that have proved useful in detection of BRSV antigen are fluorescent antibody and immunoperoxidase staining.

Paired serum samples can be used to establish a diagnosis. However, the antibody titer of animals with well-developed clinical disease may be higher in the acute sample than in the sample taken 2–3 wk later, because the antibody response often develops rapidly, and clinical signs follow virus infection by up to 7–10 days. Single serum samples with high antibody titers from a number of animals in a respiratory outbreak may help diagnosis if coupled with clinical signs. Calves that become infected with BRSV in the presence of passively derived antibody may not seroconvert.

Treatment and Prevention: Treatment focuses on antimicrobial therapy to control secondary bacterial pneumonia (*see* p 1436). There is no specific treatment for the viral interstitial pneumonia. Supportive therapy and correction of dehydration may be necessary. There are anecdotal reports of treatment with antihistamines and/or corticosteroids being of benefit. Most animals will recover in several days without treatment.

General control and prevention are discussed under ENZOOTIC PNEUMONIA OF CALVES AND SHIPPING FEVER PNEUMONIA, p 1431. Inactivated and modified-live vaccines are available and may serve to reduce losses associated with BRSV; however, there is a paucity of field trials to evaluate the efficacy of these vaccines.

Bovine Herpesvirus 1

(Infectious bovine rhinotracheitis virus, Infectious pustular vulvovaginitis, and associated diseases)

Etiology and Epidemiology: Bovine herpesvirus 1 (BHV-1) is associated with several diseases in cattle: infectious bovine rhinotracheitis (IBR), infectious pustular vulvovaginitis (IPV), balanoposthitis, conjunctivitis, abortion, encephalomyelitis, and mastitis. Only a single serotype of BHV-1 is recognized; however, three subtypes of BHV-1 have been described on the basis of endonuclease cleavage patterns of viral DNA: BHV-1.1 (respiratory subtype), BHV-1.2 (genital subtype), and BHV-1.3 (encephalitic subtype). BHV-1.3 has been reclassified as a distinct herpesvirus designated BHV-5.

BHV-1 infections are widespread in the cattle population. In feedlot cattle, the respiratory form is most common. The viral infection alone is not life-threatening but predisposes to secondary bacterial pneumonia, which may result in death. In breeding cattle, abortion or genital infections are more common. Genital infections can occur in bulls (infectious pustular balanoposthitis) and cows (IPV) within 1–3 days of mating or close contact with an infected animal. Transmission can occur in the absence of visible lesions and through artificial insemination with semen from subclinically infected bulls. Cattle with latent BHV-1 infections generally show no clinical signs when the virus is reactivated, but they serve as a source of infection for other susceptible animals.

Clinical Findings: The incubation period for the respiratory and genital forms is 2–6 days. In the respiratory form, clinical signs range from mild to severe, depending on the presence of secondary bacterial pneumonia. Clinical signs include high fever, anorexia, coughing, excessive salivation, nasal discharge that progresses from serous to mucopurulent, conjunctivitis with lacrimal discharge, inflamed nares (hence the common name “red nose”), and dyspnea

if the larynx becomes occluded with purulent material. Nasal lesions consist of numerous clusters of grayish necrotic foci on the mucous membrane of the septal mucosa, just visible inside the external nares. They may later be accompanied by pseudodiphtheritic yellowish plaques. Conjunctivitis with corneal opacity may occur as the only manifestation of BHV-1 infection. In the absence of bacterial pneumonia, recovery generally occurs 4–5 days after the onset of signs.

Abortions may occur concurrently with respiratory disease but may be seen up to 100 days after infection. They can occur regardless of the severity of disease in the dam. Abortions generally occur during the second half of pregnancy, but early embryonic death is possible.

In genital infections, the first signs are frequent urination, elevation of the tailhead, and a mild vaginal discharge. The vulva is swollen, and small papules, then erosions and ulcers, are present on the mucosal surface. If secondary bacterial infections do not occur, animals recover in 10–14 days. With bacterial infection, there may be inflammation of the uterus and transient infertility, with purulent vaginal discharge for several weeks. In bulls, similar lesions occur on the penis and prepuce. (See also p 1391.)

BHV-1 infection can be severe in young calves and cause a generalized disease. Pyrexia, ocular and nasal discharges, respiratory distress, diarrhea, incoordination, and eventually convulsions and death may occur in a short period after generalized viral infection.

Lesions: In uncomplicated IBR infections, most lesions are restricted to the upper respiratory tract and trachea. Petechial to ecchymotic hemorrhages may be found in the mucous membranes of the nasal cavity and the paranasal sinuses. Focal areas of necrosis develop in the nose, pharynx, larynx, and trachea. The lesions may coalesce to form plaques.

The sinuses are often filled with a serous or serofibrinous exudate. As the disease progresses, the pharynx becomes covered with a serofibrinous exudate, and blood-tinged fluid may be found in the trachea. The pharyngeal and pulmonary lymph nodes may be acutely swollen and hemorrhagic. The tracheitis may extend into the bronchi and bronchioles; when this occurs, epithelium is sloughed in the airways. The viral lesions are often masked by secondary bacterial infections. In young animals with generalized BHV-1 infection, erosions and ulcers overlaid with debris may be found in the nose,

esophagus, and forestomachs. In addition, white foci may be found in the liver, kidney, spleen, and lymph nodes. Aborted fetuses may have pale, focal, necrotic lesions in all tissues, which are especially visible in the liver.

Diagnosis: Uncomplicated BHV-1 infections can be diagnosed based on the characteristic signs and lesions. However, because the severity of disease can vary, it is best to differentiate BHV-1 from other viral infections by viral isolation. Samples should be taken early in the disease, and a diagnosis should be possible in 2–3 days. A rise in serum antibody titer also can be used to confirm a diagnosis. It is not possible to detect a rising antibody titer in abortions, because infection generally occurs a considerable length of time before the abortion, and titers are already maximal. BHV-1 abortion can be diagnosed by identifying characteristic lesions and demonstrating the virus in fetal tissues by PCR, virus isolation, immunoperoxidase, or fluorescent antibody staining. Gross and microscopic lesions detected shortly after death may help to establish a diagnosis. PCR methods can be used to identify antigen in a variety of tissues or exudates.

Treatment and Control: Antimicrobial therapy is indicated to prevent or treat secondary bacterial pneumonia. General recommendations for control are discussed under SHIPPING FEVER PNEUMONIA, p 1432. Immunization with modified-live or inactivated virus vaccines generally provides adequate protection against clinical disease. Both IM and intranasal modified-live vaccines are available, but the IM types may cause abortion in pregnant cattle. The intranasal vaccines can be used in pregnant cattle. The IM vaccines are easier to use and often are the vaccines of choice in feedlots. Breeding and replacement heifers and bulls should be immunized when 6–8 mo old, before breeding, and yearly thereafter. Some recommend that young bulls not be vaccinated, because they may be discriminated against when sold for breeding if they have antibody titers. Feeder calves should be immunized 2–3 wk before entry into the feedlot. A number of western European countries have eradicated or are attempting to eradicate BHV-1 from their domestic cattle populations. Eradication of the virus is possible by a combination of serologic surveillance, culling of reactors, biosecurity, and vaccination. To aid in eradication, deletion mutant vaccines have

been developed that permit discrimination between antibody produced in response to the vaccine and antibody produced in response to natural exposure.

Bovine Viral Diarrhea Virus

Bovine viral diarrhea virus (BVDV) is an RNA virus classified as a Pestivirus in the family Flaviviridae (see p 267). The role of BVDV in BRD as a primary pathogen has been controversial but appears to be that of a virus capable of inducing immunosuppression, which allows for development of secondary bacterial pneumonia. Seroconversion to BVDV after arriving in the feedlot has been reported to be the occurrence of respiratory disease in feedlot calves. Calves that arrive at the feedlot with high titers to BVDV have also been shown to be less likely to develop respiratory disease, and BVDV has been reported to be the virus most frequently associated with multiple viral infections of the respiratory tract of calves. Some studies have shown that the presence of a calf persistently infected with BVDV in a feedlot pen increases the risk of respiratory disease within that pen.

Treatment for acute BVDV infection is supportive and includes antimicrobials to prevent or treat bacterial pneumonia. General principles of control are discussed under ENZOOTIC PNEUMONIA OF CALVES AND SHIPPING FEVER PNEUMONIA, p 1431. Inactivated and modified-live vaccines are available for IM administration. Recently, vaccines containing both the type I and type II genotypes have become available. Vaccination of cows before breeding with modified-live vaccines is an important strategy to prevent the occurrence of persistently infected calves. Testing for persistently infected calves and removing them from the pen has been used as a strategy to reduce the risk of disease within feedlots in high-risk groups.

Other Bovine Respiratory Viruses

Several other viruses may potentially be involved in BRD. Bovine herpesvirus 4 has been implicated in several diseases, including BRD. Bovine adenovirus has been associated with a wide spectrum of diseases, with bovine adenovirus type 3 being the serotype most often associated with BRD. Two serotypes of bovine rhinovirus have been recognized to cause respiratory tract infections in cattle. Other viruses reported to be associated with BRD

include bovine reovirus, enterovirus, and coronavirus. Evidence is growing that bovine coronavirus may have a more important role in BRD than previously recognized. Bovine coronavirus may play a role in some outbreaks of calf pneumonia on pasture in beef cow-calf operations.

These viruses have a role similar to that of the other viruses previously discussed; ie, in combination with other stressors, they can serve as initiators of bacterial pneumonia. Vaccines are not available for prevention of these viral respiratory diseases.

BACTERIAL PNEUMONIA

Mannheimia haemolytica–associated Bovine Respiratory Disease

Etiology: *Mannheimia haemolytica* serotype 1 is the bacterium most frequently isolated from the lungs of cattle with BRD. Although less frequently cultured, *Pasteurella multocida* is also an important cause of bacterial pneumonia. *Histophilus somni* is being increasingly recognized as an important pathogen in BRD; these bacteria are normal inhabitants of the nasopharynx of cattle (see p 754). When pulmonary abscessation occurs, generally in association with chronic pneumonia, *Trueperella pyogenes* is frequently isolated.

Under normal conditions, *M haemolytica* remains confined to the upper respiratory tract, in particular the tonsillar crypts, and is difficult to culture from healthy cattle. After stress or viral infection, the replication rate of *M haemolytica* in the upper respiratory tract increases rapidly, as does the likelihood of culturing the bacterium. The increased bacterial growth rate in the upper respiratory tract, followed by inhalation and colonization of the lungs, may occur because of suppression of the host's defense mechanism related to environmental stressors or viral infections. It is during this log phase of growth of the organism in the lungs that virulence factors are elaborated by *M haemolytica*, such as an exotoxin that has been referred to as leukotoxin. The interaction between the virulence factors of the bacteria and host defenses results in tissue damage with characteristic necrosis, thrombosis, and exudation, and in the development of pneumonia. The pathogenesis of pneumonia caused by *P multocida* is poorly understood. This organism may opportunistically colonize lungs with chronically damaged respiratory defenses, such as occurs with enzootic calf pneumonia or existing lung

lesions of feedlot cattle, and cause a purulent bronchopneumonia. *H. somni* may invade the lung and cause pneumonia after damage to the respiratory defenses. This organism is capable of systemic spread from the lung to the brain, myocardium, synovium, and pleural and pericardial surfaces; often, death can occur later in the feeding period (40–60 days after arrival) from involvement of these additional organ systems.

Clinical Findings: Clinical signs of bacterial pneumonia are often preceded by signs of viral infection of the respiratory tract. With the onset of bacterial pneumonia, clinical signs increase in severity and are characterized by depression and toxemia. A combination of clinical signs of depression and fever (104°–106°F [40°–41°C]), without any signs attributable to other body systems, are the classic components of a case definition for early cases of BRD. Serous to mucopurulent nasal discharge; moist cough; and a rapid, shallow respiratory rate may be noted. Auscultation of the cranioventral lung field reveals increased bronchial sounds, crackles, and wheezes. In severe cases, pleurisy may develop, characterized by an irregular breathing pattern and grunting on expiration. The animal will become unthrifty in appearance if the pneumonia becomes chronic, which is usually associated with formation of pulmonary abscesses.

Lesions: *M. haemolytica* causes a severe, acute, hemorrhagic fibrinonecrotic pneumonia. The pneumonia has a bronchopneumonic pattern. Grossly, there are extensive reddish black to grayish brown cranioventral regions of consolidation with gelatinous thickening of interlobular septa and fibrinous pleuritis. There are extensive thromboses, foci of lung necrosis, and limited evidence of bronchitis and bronchiolitis.

P. multocida is associated with a less fulminating fibrinous to fibrinopurulent bronchopneumonia. In contrast to *M. haemolytica*, *P. multocida* is associated with only small amounts of fibrin exudation, some thromboses, limited lung necrosis, and suppurative bronchitis and bronchiolitis.

H. somni infection of the lungs results in purulent bronchopneumonia that may be followed by septicemia and infection of multiple organs. *H. somni* is associated with extensive fibrinous pleuritis in feedlot calves.

Pulmonary abscessation can occur as the pneumonia becomes chronic. Abscesses develop in ~3 wk but do not become

encapsulated until 4 wk. *T. pyogenes* is frequently cultured from these abscesses.

Diagnosis: Generally, neither serologic testing nor direct bacterial detection are performed, and diagnosis relies on gross necropsy findings and bacterial culture. Because the bacteria involved are normal inhabitants of the upper respiratory tract, the specificity of culture can be increased by collecting antemortem specimens from the lower respiratory tract by tracheal swab, transtracheal wash, or bronchoalveolar lavage. Lung specimens can be collected for culture at necropsy. If possible, specimens for culture should be collected from animals that have not been treated with antibiotics to permit determination of antimicrobial sensitivity patterns. A multiplex PCR has been used to identify a number of bacterial agents implicated with bovine respiratory disease, including *M. haemolytica*.

Treatment: Early recognition by trained personnel skilled at detecting the early clinical signs of disease followed by treatment with antibiotics is essential for successful therapy. Treatment protocols should be established so the producer has a standardized approach to identifying and treating cases. Long-acting antimicrobials such as tulathromycin, tilmicosin, florfenicol, and enrofloxacin have label claims to treat BRD and are commonly used as first- or second-line treatment options in feedlot calves. These long-acting antimicrobials allow the feedlot producer to avoid commingling sick animals in a hospital pen, and treated animals can return directly to the home pen. NSAIDs have been shown to be a beneficial ancillary therapy in controlling fever in cases of BRD, but data are lacking in terms of effect on relapse and mortality outcomes. If selection for treatment is late and pulmonary abscessation has occurred, it is difficult to achieve resolution with antimicrobials, and use of a convalescent pen or culling of the animal should be considered.

Control: General principles of control are discussed under ENZOOTIC PNEUMONIA OF CALVES AND SHIPPING FEVER PNEUMONIA, p 1431. The value of *M. haemolytica* and *P. multocida* bacterins is questionable, and some reports indicate they may even exacerbate the disease. Newer vaccines, which include live culture and subunit vaccines (leukotoxin), show much more promise for disease prevention and may reduce morbidity in

high-risk feedlot calves given one dose of vaccine on arrival by as much as 25%; however, trials have not been consistent in all risk categories of feedlot cattle. Ideally, vaccination should be done 3 wk before transport to the feedlot and can be repeated on arrival. In dairy calves, vaccination of the dam may be of benefit by providing passive immunity to the calf. *H somni* bacterins are available, and there is some evidence they are effective in control of BRD in feedlot calves even when only one dose is given on arrival.

Mycoplasmal Pneumonia

Mycoplasma bovis is an emerging cause of respiratory disease and arthritis in feedlot cattle and in young dairy and veal calves. Experimental infections usually result in inapparent to mild signs of respiratory disease, but virulent strains have been identified that cause severe lung disease in calves. However, this does not preclude a synergistic role for mycoplasmas in conjunction with viruses and bacteria in BRD. Mycoplasmas can be isolated from the respiratory tract of nonpneumonic calves, but the frequency of isolation is greater in those with respiratory tract disease. *M bovis* has been associated with otitis media in young calves and a syndrome involving chronic pneumonia and polyarthritis in feedlot cattle. These cattle invariably have a pneumonic lesion, and 40%–60% may also develop a polyarthritis and tenosynovitis that causes severe chronic lameness. The condition results in a chronic disease that does not respond to antimicrobial therapy. A significant proportion of these animals are euthanized because of the chronic nature of the disease. Lesions include chronic bronchopneumonia with caseous and coagulative necrosis. In severe cases, >80% of the lung tissue may be involved. Culture of these organisms requires special media and conditions; growth of the organisms may take up to a week. PCR tests are now available that can detect the mycoplasma within hours, thus greatly speeding up diagnosis. Immunohistochemical tests can also be done on fixed tissue that link the mycoplasma antigen directly with the lung lesion. Vaccines are commercially available for *M bovis*, but their efficacy has not been demonstrated conclusively.

Chlamydial Pneumonia

Chlamydial agents have been implicated in a number of diseases of cattle, including pneumonia. Clinical signs and lesions of

bronchopneumonia have been produced by experimental infections. A synergism between *Chlamydia* and *Mannheimia haemolytica* has been demonstrated experimentally. Because this pathogen is infrequently tested for, its overall importance remains undetermined. The organism can be tested for by staining sections of lung lesions with Gimenez stain or by fluorescent antibody. Isolation requires inoculation of yolk sacs of embryonating chicks. Chlamydial agents are sensitive to tetracyclines. (See also p 598.)

CONTAGIOUS BOVINE PLEUROPNEUMONIA

Contagious bovine pleuropneumonia is highly contagious and generally accompanied by pleurisy. It is present in Africa, with minor outbreaks occurring in the Middle East. The USA has been free of the disease since 1892, the UK since 1898, and Australia since 1973. The last outbreak of CBPP in Europe was seen in Portugal in 1999. Little is known about the disease in Asia, but China claims that its last outbreak was in 1995.

Etiology: The causal organism is *Mycoplasma mycoides mycoides* small colony type. (See also p 1474.) Susceptible cattle become infected by inhaling droplets disseminated by coughing in affected cattle. Small ruminants and wildlife are not important in the epidemiology. Sheep and goats can be naturally infected but have no associated pathology. The organism can also be found in saliva, urine, fetal membranes, and uterine discharges. Transplacental infection of the fetus can occur. Viability of the organism in the environment is poor. The incubation period varies, but most cases occur 3–8 wk after exposure. In some localities, susceptible herds may show up to 70% morbidity, but much lower infection rates (~10%) associated with clinical signs are more common. Mortality is likely to be ~50% in herds experiencing the disease for the first time. Of recovered animals, 25% may become carriers with chronic lung lesions in the form of sequestra of variable size. Because carriers may not be detectable clinically or serologically, they constitute a serious problem in control programs. Breed susceptibility, management systems, and general health of the animal are important factors that influence the infection.

Clinical Findings: In acute cases, signs include fever up to 107°F (41.5°C);

anorexia; and painful, difficult breathing. In hot climates, the animal often stands by itself in the shade, its head lowered and extended, its back slightly arched, and its elbows turned out. Percussion of the chest is painful; respiration is rapid, shallow, and abdominal. If the animal is forced to move quickly, the breathing becomes more distressed and a soft, moist cough may result. The disease progresses rapidly, animals lose condition, and breathing becomes very labored, with a grunt at expiration. The animal becomes recumbent and dies after 1–3 wk. Chronically affected cattle usually exhibit signs of varying intensity for 3–4 wk, after which the lesions gradually resolve and the animals appear to recover. Subclinical cases occur and may be important as carriers. Infected calves may present primarily with polyarthritis that is seen as swelling of joints and lameness.

Lesions: The thoracic cavity may contain up to 10 L of clear yellow or turbid fluid mixed with fibrin flakes, and the organs in the thorax are often covered by thick deposits of fibrin. The disease is largely unilateral, with more than 80%–90% of cases affecting only one lung. The affected portion is enlarged and solid. On section of the lung, the typical marbled appearance of pleuropneumonia is evident because of the widened interlobular septa and subpleural tissue that encloses gray, yellow, or red consolidated lung lobules. Microscopically, this is a severe, acute, fibrinous pneumonia with fibrinous pleurisy, thrombosis of pulmonary blood vessels, and areas of necrosis of lung tissue; the interstitial tissue is markedly thickened by edema fluid containing much fibrin. In chronic cases, the lesion has a necrotic center sequestered in a thick, fibrous capsule, and there may be fibrous pleural adhesions. Organisms may survive only within the inner capsule of these sequestra, and these animals may become carriers.

Diagnosis: Diagnosis is based on clinical signs and the characteristic gross pathological lesions of the lungs. Complement fixation, latex agglutination, or competitive ELISA tests can be used to aid definitive diagnosis. Confirmation is often by isolation of the mycoplasma followed by growth inhibition or immunofluorescence test using hyperimmune rabbit sera against the mycoplasma, or increasingly by PCR. Confirmation of serologic reactions can be

made by immunoblotting test. As soon as an outbreak is suspected, slaughter and necropsy of presumptively infected cattle is advisable.

Control: The disease is reportable by law in many countries from which it has been eradicated by slaughter of all infected and exposed animals. In countries where cattle movement can readily be restricted, the disease can be eradicated by quarantine, blood testing, and slaughter. Where cattle cannot be confined, the spread of infection can be limited by immunization with attenuated vaccine (eg, T1/44 strain). However, the vaccine is effective only if herd coverage within a country is high. Tracing the source of infected cattle detected at abattoirs, blood testing, and imposition of strict rules for cattle movement also can aid in control of the disease in such areas.

Treatment is recommended only in endemic areas because the organisms may not be eliminated, and carriers may develop. Tylosin (10 mg/kg, IM, bid, for six injections) and danofloxacin 2.5% (2.5 mg/kg/day for 3 consecutive days) have been reported to be effective.

INTERSTITIAL PNEUMONIA

This classification represents a group of respiratory diseases characterized by an acute onset of severe respiratory distress and a combination of lung lesions that include pulmonary edema and congestion, interstitial emphysema, alveolar epithelialization, and hyaline membrane formation.

Lungworm infection in cattle (*see* p 1421) can also result in an atypical interstitial pneumonia.

ACUTE BOVINE PULMONARY EMPHYSEMA AND EDEMA

(Fog fever, Bovine atypical interstitial pneumonia)

Acute bovine pulmonary emphysema and edema (ABPEE) is one of the more common causes of acute respiratory distress in cattle, particularly adult beef cattle, and is characterized by sudden onset, minimal coughing, and a course that ends fatally or improves dramatically within a few days. It is a disease involving groups of cattle; morbidity may be >50%, although usually only a small minority develops severe respiratory distress. Typically, ABPEE occurs in the fall, 5–10

days after change to a better, often lush, pasture. A similar condition has been reported when cattle are fed on a wide variety of grasses, alfalfa, rape, kale, and turnip tops.

Etiology: Metabolites of the naturally occurring amino acid L-tryptophan probably are responsible for many outbreaks. In the rumen, L-tryptophan is degraded to indoleacetic acid, which can be converted to 3-methylindole by some ruminal microorganisms. 3-Methylindole is absorbed into the bloodstream and is the source of the pneumotoxicity after metabolism by the mixed function oxidase system, which is very active in the lungs. Apparently, the level of L-tryptophan in crops is most likely to be high in lush, rapidly growing pastures, particularly (but not exclusively) in the fall.

Clinical Findings: ABPEE is most common in adult beef cows but may occur in either sex and in dairy or beef cattle under similar management conditions. Nursing calves are unaffected. Outbreaks usually develop within 5–10 days of a change to better grazing and rarely occur in animals that have been on a field >3 wk.

Mild cases may go unnoticed. Cattle are subdued but still alert; there is tachypnea and hyperpnea, but auscultation is usually unrewarding. Such cattle usually recover spontaneously within days. Severely affected cattle show extensive respiratory distress with mouth breathing, extension of the tongue, and drooling. A loud expiratory grunt is common, but coughing is unusual. In the early stages, auscultation reveals surprisingly soft respiratory sounds. Mild exercise increases dyspnea and may precipitate death. If death does not occur, the animals improve dramatically and resume eating by the third day. At this stage, auscultation reveals harsh respiratory sounds and, in some animals, dorsal (emphysematous) crackles. Some cattle have subcutaneous emphysema extending along the back from the withers. Full clinical recovery may require 3 wk.

Lesions: In affected cattle that have died or been slaughtered in extremis, the lungs are heavy and do not collapse normally. They are widely affected, with various degrees of firmness; there is extensive edema and emphysema, often with the formation of large, air-filled

bullae in interlobular and subpleural regions. Submucosal hemorrhages are often present on the larynx and in the trachea and larger bronchi. Histologically, the lesion is characterized by congestion, alveolar edema, hyaline membrane formation, and areas of early alveolar epithelial hyperplasia of type II pneumocytes; occasionally, areas of bronchiolar necrosis may be found. The emphysema is often dramatic and is limited to interstitial fascia, where it is accompanied by edema.

In animals slaughtered after 3 days of illness, the lungs are still heavy and do not collapse normally. They are pinkish gray and of increased firmness; edema and emphysema are inconspicuous or absent. Histologically, widespread alveolar epithelial hyperplasia characteristic of a diffuse, acute, proliferative alveolitis is seen.

Diagnosis: Diagnosis is based on history, signs, and lesions. Because the syndrome is not specific with regard to cause, evidence must be obtained from history of management factors such as change in pasture.

Treatment: Severely affected animals have so little pulmonary reserve that any driving or handling must be done with caution to prevent immediate death. Removal of cattle from the offending pastures may not prevent the development of new cases for the next 4–7 days. No treatment has been identified that will reverse the fully developed lesions of ABPEE.

Control: One approach to control is dietary management, including the following options: 1) avoiding pastures likely to induce ABPEE, 2) feeding hay before turn out on pasture and limiting exposure time on suspect pastures, 3) limiting grazing time and gradually increasing exposure to the pasture over time, 4) using pastures before they become lush, 5) delaying use of lush pastures until after a hard frost, 6) initially grazing pastures with less susceptible stock (cattle <15 mo old or sheep), or 7) using strip grazing.

A medical approach to control involves feeding monensin or lasalocid, which inhibit the bacteria that convert L-tryptophan to 3-methylindole. Treatment with monensin can be started 1 day before introduction to pasture, whereas lasalocid requires a 6-day pretreatment period. These drugs are of no benefit after onset of clinical signs.

ANAPHYLAXIS

Anaphylaxis or Type I hypersensitivity reactions in cattle can result in an atypical interstitial pneumonia. The lung is a major target organ in cattle for Type I hypersensitivity. Clinical signs are those of acute respiratory distress. Cattle that die of anaphylaxis may have lesions consistent with those described for atypical interstitial pneumonia. Treatment is administration of epinephrine; supportive treatment includes anti-inflammatory therapy with corticosteroids or NSAIDs. If pharyngeal or laryngeal edema is present, a tracheostomy may be indicated.

HYPERSENSITIVITY PNEUMONITIS

(Extrinsic allergic alveolitis, Farmer's lung disease)

Hypersensitivity pneumonitis is a condition that appears to be similar to farmer's lung disease in people and occurs in both acute and chronic forms in adult cattle. The human and bovine forms of the disease may coexist on problem farms because of common exposure to dust from moldy hay.

Etiology: The disease occurs when sensitized individuals inhale antigens from thermophilic actinomycetes, commonly the spores of *Micropolyspora faeni*. The actinomycetes proliferate in vast numbers in hay, grain, or other vegetable material that has overheated to ~150°F (65°C) after damp storage (30%–40% moisture content). Dust that contains large numbers of spores is released when this moldy hay is shaken. The small size (1 µm) of the spores allows them to reach the smallest airways and alveoli to provoke a reaction that has been termed a "hypersensitivity pneumonitis"; this is considered to be predominantly a Type III hypersensitivity reaction, although a Type IV hypersensitivity component is suspected (see IMMUNOLOGIC DISEASES, p 817 et seq).

Affected herds are found in areas where rainfall is usually significant during the haymaking season, suggesting that a clinical problem may arise only after repeated sensitization and challenge from the spores. Clinical disease tends to arise during the latter half of the winter feeding period and usually only when moldy hay is fed indoors. Under such circumstances, serum antibodies (usually detected by

immunodiffusion) to *M. faeni* are widespread among adult cattle by the end of each winter feeding period, and many apparently healthy cattle are seropositive. By contrast, few adult cattle are seropositive on other farms on which "good" hay or grass silage is fed.

Clinical Findings: Cattle may succumb to the acute form of the disease over a period of weeks. Usually, only severe acute cases are noticed. There is respiratory distress, anorexia, and agalactia in animals ≥5 yr old; coughing and pyrexia also occur, and adventitious sounds are occasionally heard on auscultation. Death is rare.

The chronic disease usually has a higher morbidity; in most instances, the signs are weight loss, poor production, and persistent coughing. Affected cattle are fairly bright and eat reasonably well, but tachypnea, hyperpnea, and coughing are widespread. Auscultation may reveal cranioventral crackles and sometimes, in more severe cases, scattered rhonchi. Exercise intolerance may be seen, and congestive cardiac failure can develop if pulmonary fibrosis is widespread.

Lesions: The macroscopic lesions are often unremarkable; usually, there is mild peripheral lobular overinflation with diffusely scattered, small, gray, subpleural spots. Although transient pulmonary edema may be a feature of severe acute cases, the histologic lesions consistently found are interalveolar cellular infiltration, epithelioid granulomata, and bronchiolitis obliterans. In some chronic cases, small foci of alveolar epithelial hyperplasia and metaplasia with interstitial fibrosis are found. These areas may extend to include most, if not all, of the lung substance to produce cases clinically indistinguishable from diffuse fibrosing alveolitis (see below). Circumstantial evidence suggests that some cases of diffuse fibrosing alveolitis are the end stage of hypersensitivity pneumonitis.

Treatment and Control: Because it is often impossible to completely shield cattle from further challenge, most recover only partially after dexamethasone treatment (1 mg/5–10 kg body wt). However, improvement is usually marked when cattle are turned out in the spring. Prevention is difficult in areas where hay is likely to be wet during the curing process and it is not possible to alter the feeding regimen.

DIFFUSE FIBROSING ALVEOLITIS

Diffuse fibrosing alveolitis is a chronic, progressive respiratory disease of undetermined cause and possibly of multiple etiologies. A proportion of affected cattle are seropositive for precipitating antibodies to *Micropolyspora faeni*, and this condition may represent the end stage of hypersensitivity pneumonitis. Other than the respiratory signs, the animals appear alert and maintain a good appetite until the onset of heart failure in the terminal stages. Signs include coughing, increased respiratory rate, dyspnea, and weight loss. Necropsy findings include right ventricular hypertrophy, interalveolar fibrosis, obliteration of the alveolar spaces, alveolar hyperplasia, bronchitis, and bronchiolitis. There is no treatment.

ACUTE RESPIRATORY DISTRESS SYNDROME OF FEEDLOT CATTLE

An acute respiratory distress syndrome has been described in feedlot cattle with clinical signs and pathologic findings of an atypical interstitial pneumonia. The syndrome occurs sporadically, and the etiology remains undefined. Feedlot heifers seem to be at higher risk of developing the disease than feedlot steers. Bovine respiratory syncytial virus, abnormal production of 3-methylindole in the rumen, dusty conditions, and preexisting lesions of chronic cranioventral bacterial pneumonia have been suggested as causes or contributing factors. Clinical signs include respiratory distress characterized by tachypnea and dyspnea, and affected cattle may be found dead if clinical signs are unobserved. Lesions are those of atypical interstitial pneumonia with prominent emphysema and edema in the lungs. Treatment protocols have not been defined; thus, treatment is symptomatic and supportive. In many cases, emergency slaughter is the most economical option. Management strategies suggested include vaccinating for bovine respiratory syncytial virus, controlling dust in the feedlot, and avoiding abrupt dietary changes.

4-IPOMEANOL TOXICITY (MOLDY SWEET POTATO) AND PERILLA KETONE TOXICITY (PURPLE MINT TOXICITY)

Clinicopathologic syndromes indistinguishable from acute bovine pulmonary emphysema and edema (ABPEE, see p 1439) occur after ingestion of either moldy sweet potatoes infested with

Fusarium solani, or the wild mint *Perilla frutescens*. Moldy sweet potato toxicity is caused by the ingestion of a furanoterpenoid toxin produced by sweet potatoes (*Ipomoea batatas*) in response to infestation with the fungus *F. solani*; the end result is production of the pneumotoxin 4-ipomeanol. *Perilla* ketone toxicity is caused by ingestion of the leaves and seeds of the plant *P. frutescens* (purple mint), which contains a pneumotoxin and is found in the southeastern USA. The pathogenesis of both these conditions are similar to that of ABPEE, as is approach to treatment.

TOXIC GASES

Nitrogen dioxide is a major component of silo gas; in people, the disease associated with exposure to NO₂ is termed silo filler's disease. Exposure of cattle results in respiratory distress and necropsy findings of atypical interstitial pneumonia. Treatment is empirical and includes diuretics, corticosteroids, and antibiotics to prevent pneumonia.

Zinc oxide is produced during oxyacetylene cutting or arc welding of galvanized pipes. These activities in closed facilities in which cattle are housed may result in toxicity characterized by respiratory distress. Lesions are similar to those described for atypical interstitial pneumonia. Treatment is as described for nitrogen dioxide toxicity.

VENA CAVAL THROMBOSIS AND METASTATIC PNEUMONIA

Etiology: Vena caval thrombosis and metastatic pneumonia is associated with multifocal abscesses in the lung as the result of septic embolism of the pulmonary arterial vascular system arising from septic thrombi in the caudal vena cava. The most common cause of vena caval thrombosis is ruminal acidosis leading to rumenitis and subsequent liver abscessation, which may result in a thrombus in the caudal vena cava if the vessel wall is infiltrated by the abscess. Bacteria most frequently involved include *Fusobacterium necrophorum*, *Trueperella pyogenes*, staphylococci, streptococci, and *Escherichia coli*.

Clinical Findings: The condition usually occurs in adult dairy cattle or in feedlot

cattle on high-carbohydrate diets. Presenting signs can be acute, manifested by respiratory distress, or chronic, manifested by weight loss and chronic coughing.

A common presentation is tachypnea, tachycardia, hemic murmurs, coughing, pale mucous membranes, increased lung sounds, hemoptysis, and epistaxis. Pyrexia and melena may also be present. The case fatality rate is essentially 100%.

Lesions: A thrombus is found in the vena cava, and hepatic abscesses may be noted. A suppurative pneumonia is present with pulmonary abscesses,

aneurysms, and blood clots from ruptured aneurysms found throughout the entire lung parenchyma. The generalized distribution of these lesions caused by hematogenous spread is characteristic of this condition.

Treatment and Control: Because of the poor prognosis, treatment is not indicated. If attempted, treatment includes antibiotics and supportive therapy. Control efforts should focus on reducing the incidence of ruminal acidosis, which can result in rumenitis and subsequent formation of liver abscesses.

RESPIRATORY DISEASES OF HORSES

Viral respiratory infections are common in horses; the most notable are equine herpesvirus infection, equine influenza, and equine viral arteritis. The clinical manifestations are similar and include pyrexia, serous nasal discharge, submandibular lymphadenopathy, anorexia, and cough. In addition to respiratory disease, equine herpesvirus type 1 (EHV-1) can cause abortion and neurologic disease, and equine herpesvirus type 5 (EHV-5) is a newly recognized cause of multinodular pulmonary fibrosis. Equine viral arteritis produces respiratory disease, vasculitis, and abortion. Equine herpesvirus type 2 (EHV-2), equine rhinitis virus, and reovirus are ubiquitous viral respiratory pathogens, and infection results in minimal clinical disease. Adenovirus pneumonia is most often seen in association with severe combined immunodeficiency in Arabian foals. Hendra virus (see p 1448) is a zoonotic disease of horses identified in Australia; it is rapidly fatal in horses, and close contact is necessary for disease transmission.

Secondary bacterial respiratory infections are primarily initiated by viral disease, because viral respiratory infections impair and/or destroy respiratory defense mechanisms (ie, influenza destroys the mucociliary apparatus, EHV destroys bronchial-associated lymphoid tissue). The most common organisms associated with pneumonia in horses are opportunistic bacteria originating from the resident microflora of the upper respiratory tract. Clinical evidence of a secondary bacterial infection includes mucopurulent nasal discharge, depression, persistent fever,

abnormal lung sounds, hyperfibrinogenemia, and leukocytosis. Secondary bacterial disease may result in mucosal bacterial infections (rhinitis and tracheitis) or may produce more serious invasive disease such as pneumonia and pleuropneumonia.

Streptococcus equi zooepidemicus is the most common opportunistic pathogen of the equine lung, although *Actinobacillus equuli*, *Bordetella bronchiseptica*, *Escherichia coli*, *Pasteurella* spp, and *Pseudomonas aeruginosa* are frequently isolated. *S equi equi*, the causative agent of strangles (see p 1453), is a primary bacterial pathogen of the upper respiratory tract and is capable of mucosal invasion without predisposing factors. *Rhodococcus equi* is a primary pathogen of the lower respiratory tract of foals and produces pulmonary consolidation and abscessation. *R equi* pneumonia has been reported in adult horses with a compromised immune system.

Noninfectious respiratory disease is a common, performance-limiting condition that affects adult horses of various ages.

Inflammatory airway disease is characterized by excessive tracheal mucus, airway hyperreactivity, and poor exercise performance in young horses. The etiology is unclear, but viral respiratory infection (EHV-2), allergy, and environmental factors may play a role in the pathophysiology.

Reactive airway disease (heaves) is triggered by exposure to organic dusts in older horses with a genetic predisposition to allergic airway disease. Small airways are obstructed by bronchoconstriction and

excessive mucus production. The severity of clinical signs ranges from exercise intolerance to dyspnea at rest.

The respiratory system is one of the most accessible body systems to test diagnostically. Endoscopic examination allows direct visualization of the upper respiratory tract, guttural pouches, trachea, and mainstem bronchi. Indications for endoscopic examination include upper airway noise, inspiratory difficulty, poor exercise performance, and unilateral or bilateral nasal discharge. Radiographs of the skull are indicated to investigate facial deformity, abnormalities of the sinus (sinusitis, dental abnormalities, and sinus cyst), guttural pouch (empyema, tympany), and soft-tissue structures (epiglottitis, soft palate). The most important techniques for evaluation of lower respiratory tract secretions are transtracheal wash and bronchoalveolar lavage. Transtracheal wash is indicated to obtain secretions for bacterial and fungal culture of the lower respiratory tract. Bronchoalveolar lavage is indicated for cytologic evaluation of the lower respiratory tract in animals with diffuse, noninfectious pulmonary disease. Nasal swab culture is inappropriate for investigation of pulmonary infectious disease but is indicated for horses with suspected strangles infection.

Thoracic radiography and ultrasonography are valuable for assessing lower respiratory tract disease. Thoracic radiography is used to identify abnormalities of the pulmonary parenchyma, mediastinum, and diaphragm. Pulmonary consolidation (pneumonia), peribronchial disease, pulmonary abscessation, interstitial disease, and mediastinal masses (neoplasia, abscess, granuloma) are most easily identified via thoracic radiography. Thoracic ultrasonography is the most appropriate technique to evaluate fluid in the pleural space, peripheral pulmonary consolidation, and peripheral pulmonary abscessation. Ultrasonographic examination can identify the volume, location, and character of pleural fluid or air within the pleural space (pneumothorax). Additionally, it can identify fibrin tags, gas echoes (anaerobic infection), masses, and loculated fluid pockets, and it allows the clinician to determine the most appropriate site for centesis and to formulate a prognosis.

Pleurocentesis is performed in animals with accumulation of fluid in the pleural space and should be conducted with ultrasonographic guidance. Lung biopsy and fine-needle aspiration are invasive

procedures and performed only after other diagnostic procedures have been exhausted. Pulmonary neoplasia, pulmonary fibrosis, and interstitial diseases may require lung biopsy to obtain a definitive diagnosis.

Vaccination does not always prevent respiratory infections in horses, but duration and severity is usually lessened in horses that have been vaccinated regularly, depending on factors such as the disease and specific vaccine. Vaccines are commercially available for equine influenza, viral rhinopneumonitis, equine viral arteritis, and strangles. The cost and hazards of each vaccination must be weighed against the probability of exposure and potential disease. Vaccination recommendations and schedules vary according to use of the horse and its potential for exposure to contagious animals. The American Association of Equine Practitioners (AAEP) Infectious Disease Committee has developed guidelines for all core and risk-based equine vaccinations; recommendations are posted on the AAEP Web site.

Regardless of the type of respiratory disease, environmental factors and supportive care are important to aid recovery. A dust and ammonia-free stable environment prevents further damage to the mucociliary apparatus. Highly palatable feeds are indicated to prevent weight loss and debilitation during the treatment and recovery period. Adequate hydration will decrease the viscosity of respiratory secretions, facilitating their removal from the lower respiratory tract. A comfortable, dry, temperature-appropriate environment will allow the horse to rest and minimize the role of the respiratory tract in thermoregulation.

EQUINE HERPESVIRUS INFECTION

(Equine viral rhinopneumonitis, Equine abortion virus)

Etiology and Epidemiology: Equine herpesvirus 1 (EHV-1) and equine herpesvirus 4 (EHV-4) comprise two antigenically distinct groups of viruses previously referred to as subtypes 1 and 2 of EHV-1. Both viruses are ubiquitous in horse populations worldwide and produce an acute febrile respiratory disease upon primary infection, characterized by rhinopharyngitis and tracheobronchitis. Outbreaks of respiratory disease occur annually among foals in areas with

concentrated horse populations. Most of these outbreaks in weanlings are caused by strains of EHV-4. The age, seasonal, and geographic distributions vary and are determined by immune status and horse population. In individual horses, the outcome of exposure is determined by viral strain, immune status, pregnancy status, and possibly age. Infection of pregnant mares with EHV-4 rarely results in abortion.

Mares may abort several weeks to months after clinical or subclinical infection with EHV-1. The neurologic form of EHV-1 has demonstrated increasing morbidity and mortality in the documented outbreaks since 2000 and appears to be evolving in virulence and behavior. Therefore, the USDA has designated neuropathic EHV-1 as a potentially emerging disease. The natural reservoir of both EHV-1 and EHV-4 is the horse. Latent infections and carrier states are seen with both virus types. Transmission occurs by direct or indirect contact with infectious nasal secretions, aborted fetuses, placentas, or placental fluids.

Clinical Findings: The incubation period of EHV is 2–10 days. Susceptible horses develop fever of 102°–107°F (38.9°–41.7°C), neutropenia and lymphopenia, serous nasal discharge, malaise, pharyngitis, cough, inappetence, and/or submandibular or retropharyngeal lymphadenopathy. Horses infected with EHV-1 strains often develop a biphasic fever, with cell-associated viremia coinciding with the second temperature peak. Secondary bacterial infections are common and manifest with mucopurulent nasal exudate and pulmonary disease. The infection is mild or inapparent in horses immunologically sensitized to the virus.

Mares that abort after EHV-1 infection seldom display premonitory signs. Abortions occur 2–12 wk after infection, usually between months 7 and 11 of gestation. Aborted fetuses are fresh or minimally autolyzed, and the placenta is expelled shortly after abortion. There is no evidence of damage to the mare's reproductive tract, and subsequent conception is unimpaired. Mares exposed late in gestation may not abort but give birth to live foals with fulminating viral pneumonitis. Such foals are susceptible to secondary bacterial infections and usually die within hours or days.

Outbreaks with specific strains of EHV-1 infection result in neurologic disease (*see p 1245*). Clinical signs vary from mild incoordination and posterior paresis to

severe posterior paralysis with recumbency, loss of bladder and tail function, and loss of skin sensation in the perineal and inguinal areas. In exceptional cases, the paralysis may progress to quadriplegia and death. Prognosis depends on severity of signs and the period of recumbency.

Lesions: The pathogenetic mechanisms of EHV-1 and EHV-4 differ significantly. EHV-4 infection is restricted to respiratory tract epithelium and associated lymph nodes; EHV-1 strains develop cell-associated viremia and have a predilection for vascular endothelium, especially the nasal mucosa, lungs, placenta, adrenal, thyroid, and CNS. The neuropathic strain of EHV-1 produces a viremic load 10- to 100-fold higher than that of non-neuropathic strains.

Gross lesions of viral rhinopneumonitis are hyperemia and ulceration of the respiratory epithelium, and multiple, tiny, plum-colored foci in the lungs. Histologically, there is evidence of inflammation, necrosis, and intranuclear inclusions in the respiratory epithelium and germinal centers of the associated lymph nodes. Lung lesions are characterized by neutrophilic infiltration of the terminal bronchioles, peribronchiolar and perivascular mononuclear cell infiltration, and serofibrinous exudate in the alveoli.

Typical lesions in EHV-1 abortion include interlobular lung edema and pleural fluid; multifocal areas of hepatic necrosis; petechiation of the myocardium, adrenal gland, and spleen; and thymic necrosis. Intranuclear inclusions are found in lung, liver, adrenal, and lymphoreticular tissues.

Horses with EHV-1-associated neurologic disease may have no gross lesions or only minimal evidence of hemorrhage in the meninges, brain, and spinal cord parenchyma. Histologically, lesions are discrete and comprise vasculitis with endothelial cell damage and perivascular cuffing, thrombus formation and hemorrhage, and in advanced cases, areas of malacia. Lesions may occur at any level of the brain or spinal cord.

Diagnosis: Equine viral rhinopneumonitis is difficult to clinically differentiate from equine influenza (*see p 1447*), equine viral arteritis (*see p 701*), or other equine respiratory infections solely on the basis of clinical signs. Definitive diagnosis is determined by PCR or virus isolation from samples obtained via nasopharyngeal swab and citrated blood sample (buffy coat) early in the course of the infection.

In cases of suspected EHV-1 abortion, definitive diagnosis is based on PCR, virus isolation, and characteristic gross and microscopic lesions in the aborted fetus. Lung, liver, adrenal, and lymphoreticular tissues are productive sources of virus. Serologic testing of mares after abortion has little diagnostic value. Diagnosis of neuropathic EHV-1 is determined by real-time PCR on samples obtained from nasal secretions, CSF, or neural tissue to detect the neuropathic strain of EHV-1. A presumptive diagnosis can be based on clinical signs and CSF analysis (xanthochromia, albuminocytologic dissociation). Necropsy reveals characteristic perivascular cuffing and hemorrhage in the CNS.

Treatment: There is no specific treatment for EHV infection. Rest and nursing care are indicated to minimize secondary bacterial complications. Antipyretics are recommended for horses with a fever $>104^{\circ}\text{F}$ (40°C). Antibiotic therapy is instituted upon suspicion of secondary bacterial infection evidenced by purulent nasal discharge or pulmonary disease. Most foals infected prenatally with EHV-1 die shortly after birth despite intensive nursing and antimicrobial medication. If horses with neuropathic EHV-1 remain ambulatory or are recumbent for only 2–3 days, the prognosis is usually favorable. Valacyclovir (30 mg/kg, PO, bid) has shown promise in the treatment of affected horses and in prophylaxis during EHV-1 outbreaks. Intensive nursing care is necessary to avoid pulmonary congestion, pneumonia, ruptured bladder, or bowel atony. Recovery may be complete, but a small percentage of cases have neurologic sequelae.

Control: Immunity after natural infection with either EHV-1 or EHV-4 involves a combination of humoral and cellular immunity. Whereas little cross-protection occurs between virus types after primary infection of immunologically naive foals, significant cross-protection develops in horses after repeated infections with a particular virus type. Most adult horses are latently infected with EHV-1 and EHV-4. The infection remains dormant for most of the horse's life, although stress or immunosuppression may result in recrudescence of disease and shedding of infectious virus. Immunity to reinfection of the respiratory tract may persist for as long as 3 mo, but multiple infections result in a level of immunity that prevents clinical signs of respiratory disease. Diminished resistance in pregnant mares allows cell-associated

viremia, which may result in transplacental infection of the fetus.

For prevention and control of EHV-4- and EHV-1-related diseases, management practices that reduce viral spread are recommended. New horses (or those returning from other premises) should be isolated for 21 days before commingling with resident horses, especially pregnant mares. Management-related, stress-inducing circumstances should be avoided to prevent recrudescence of latent virus. Pregnant mares should be maintained in a group away from the weanlings, yearlings, and horses out of training. In an outbreak of respiratory disease or abortion, affected horses should be isolated and appropriate measures taken for disinfection of contaminated premises. No horse should leave the premises for 3 wk after recovery of the last clinical case.

Vaccination (EHV-4 and EHV-1) should begin when foals are 4–6 mo old. A second dose is given 4–6 wk later, and a third dose at 10–12 mo of age. Booster vaccinations may be indicated as often as every 6 mo through maturity (5 yr of age). Vaccination programs against herpesviruses should include all horses that travel to high-risk destinations (racetrack, show grounds) and all other horses on the premises. A high-antigen load, inactivated EHV-1 vaccine is recommended to prevent EHV-1 abortion. Vaccine should be administered during months 3, 5, 7, and 9 of pregnancy. Mares are often vaccinated with inactivated EHV-1/EHV-4 at an interval 4–6 wk before foaling. A modified-live EHV-1 vaccine is available to help prevent respiratory disease caused by EHV-1.

Infection by other Herpesviruses:

Equine herpesvirus 2 (EHV-2) is ubiquitous in respiratory mucosa, conjunctiva, and WBCs of normal horses of all ages. The pathogenic significance remains obscure. It has been suggested that EHV-2 is the cause of herpetic keratoconjunctivitis and inflammatory airway disease in young horses. Equine herpesvirus 3 (EHV-3) is the cause of equine coital exanthema (see p 1357), a benign, progenital exanthematous disease.

Equine gamma herpesvirus 5 (EHV-5) has emerged as the pathogen associated with equine multinodular pulmonary fibrosis (EMPF). The role of EHV-5 in EMPF is unclear (precipitating, causative, incidental). Clinical signs include weight loss, cough, fever (variable), and respiratory difficulty. EMPF is seen primarily in middle-aged horses, although it has been reported

in young horses. Physical examination findings include tachycardia, tachypnea, increased respiratory effort (inspiratory), and poor body condition. Wheezes and crackles are often auscultated without a rebreathing procedure. In early cases, EMPF may be mistaken as heaves. In addition to EMPF, EHV-5 has been associated with lymphoproliferative disease and lymphoma. One unusual case report describes a 21-yr-old horse with profound pancytopenia and pulmonary fibrosis; EHV-5 was isolated from the bone marrow of this horse.

Diagnostic testing includes routine blood work, thoracic radiographs, and virus-specific PCR testing on pulmonary secretions (bronchoalveolar lavage) or percutaneous lung biopsy sample. CBC reveals neutrophilic leukocytosis with or without hyperfibrinogenemia and anemia. Findings on thoracic radiographs range from a moderate interstitial pattern to a severe reticulonodular pattern. Differential diagnoses of radiographic images include fungal pneumonia and metastatic neoplasia. Fungal pneumonia typically occurs after primary GI disease with neutropenia, and metastatic neoplasia is rare. The most common antemortem diagnostic test is virus-specific PCR of bronchoalveolar lavage fluid. Percutaneous, ultrasound-guided lung biopsy can be performed to confirm the diagnosis and establish a prognosis. The procedure is not without risk in dyspneic horses. Histopathology reveals multifocal granulomas, type II pneumocyte hyperplasia, and intraluminal cellular accumulation. Advanced pulmonary fibrosis indicates a poor prognosis for survival.

The prognosis for survival is ~50%. Horses with granulomatous inflammation have been successfully treated with antiviral therapy. Valacyclovir (30 mg/kg, PO, tid) and/or acyclovir (10 mg/kg, IV, in 1 L of isotonic crystalloid fluid as a constant-rate infusion over 1 hr, bid $\times$ 2 days) appear promising, although sensitivity of the virus to these medications has not been documented. Doxycycline (5–10 mg/kg, PO, once to twice daily) is administered to combat secondary bacterial infection and for its anti-inflammatory properties. Administration of corticosteroids is controversial, although they are commonly used. Corticosteroids (0.08–0.1 mg/kg, IV, every 24–48 hr) may improve disease outcome through reduction of pulmonary cytokines and inflammatory mediators, but they may also cause immunosuppression, which may enhance viral replication and disease severity.

EQUINE INFLUENZA

Etiology and Epidemiology: Equine influenza is highly contagious and spreads rapidly among naive horses. Horses 1–5 yr old are the most susceptible to infection. Orthomyxovirus A/equine-2 was first recognized in 1963 as a cause of widespread epidemics and has subsequently become endemic in many countries, except for New Zealand and Iceland. China, Japan, and Australia experienced devastating epidemics of equine influenza affecting tens of thousands of horses in 2007. Equine influenza had not been reported in China since 1993, in Japan since 1972, and had never been reported in Australia.

Endemicity is maintained by sporadic clinical cases and by inapparent infection in susceptible horses introduced into the population by birth, through waning immunity, or after movement from other areas or countries. A carrier state is not recognized for equine influenza. The clinical outcome after viral exposure largely depends on immune status; clinical disease varies from a mild, inapparent infection to severe disease in susceptible animals. Influenza is rarely fatal except in donkeys, zebras, and debilitated horses. Transmission occurs by inhalation of respiratory secretions. Epidemics arise when one or more acutely infected horses are introduced into a susceptible group. The epidemiologic outcome depends on the antigenic characteristics of the circulating virus and the immune status of a given population of horses at time of exposure. Frequent natural exposure or regular vaccination may contribute to the degree of antigenic drift seen with specific strains of A/equine-2 virus in some parts of the world.

Clinical Findings and Lesions: The incubation period of influenza is ~1–3 days. Clinical signs begin abruptly and include high fever (up to 106°F [41.1°C]), serous nasal discharge, submandibular lymphadenopathy, and coughing that is dry, harsh, and nonproductive. Depression, anorexia, and weakness are frequently seen. Clinical signs usually last <3 days in uncomplicated cases. Influenza virus replicates within respiratory epithelial cells, resulting in destruction of tracheal and bronchial epithelium and cilia. Cough develops early in the course of infection and may persist for several weeks. Nasal discharge, although scant and serous initially, may become mucopurulent due to secondary bacterial infection. Mildly affected horses recover uneventfully in 2–3 wk; severely

affected horses may convalesce as long as 6 mo. Recovery may be hastened by complete restriction of strenuous physical activity. Respiratory tract epithelium takes ~21 days to regenerate; during this time, horses are susceptible to development of secondary bacterial complications such as pneumonia, pleuropneumonia, and chronic bronchitis. Complications are minimized by restricting exercise, controlling dust, providing superior ventilation, and practicing good stable hygiene. Primary complications of vasculitis, myositis, and myocarditis are seen infrequently.

Diagnosis: The presence of a rapidly spreading respiratory infection in a group of horses characterized by rapid onset, high fever, depression, and cough is presumptive evidence of equine influenza. Definitive diagnosis can be determined by virus isolation, influenza A antigen detection (patient-side kit), or paired serum samples (hemagglutination inhibition). Nasopharyngeal swabs are obtained for virus isolation and antigen detection. These samples should be obtained soon after the onset of illness. Virus isolation in chick embryos is highly specific but less sensitive for detection of influenza because of bacterial contamination of the sample. Antigen detection is performed using a human influenza A kit, which provides immediate results that are not affected by bacterial contamination.

Treatment and Prevention: Horses that do not develop complications require rest and supportive care. Horses should be rested 1 wk for every day of fever, with a minimum of 3 wk rest (to allow regeneration of the mucociliary apparatus). NSAIDs are recommended for horses with a fever $>104^{\circ}\text{F}$ (40°C). Antibiotics are indicated when fever persists beyond 3–4 days or when purulent nasal discharge or pneumonia is present.

Prevention of influenza requires hygienic management practices and vaccination. Exposure can be reduced by isolation of newly introduced horses for 2 wk. Numerous vaccines are commercially available for prevention of equine influenza. An intranasal modified-live influenza vaccine, designed to induce mucosal (local) antibody protection, has demonstrated protection against natural challenge. This vaccine is temperature sensitive and is not capable of replicating beyond the nasal passages (ie, inactivated by core body temperature). Most commercially available influenza vaccines are inactivated, adjuvanted vaccines recommended

primarily for IM administration. A recombinant canarypox-vectored influenza vaccine has also been shown to be effective against influenza challenge. Because the duration of protection provided by current vaccines is limited, booster injections for at-risk adult horses should be administered every 6 mo. Sedentary horses can be vaccinated annually. Foals should be vaccinated with a single modified-live intranasal vaccine or a series of three inactivated vaccines beginning at 6 mo, with booster vaccination in 3–6 wk and again between 10 and 12 mo of age. Broodmares should be vaccinated 4–6 wk before foaling.

EQUINE VIRAL ARTERITIS

Equine viral arteritis (EVA) is caused by an RNA togavirus and produces clinical signs of respiratory disease, vasculitis, and abortion. Horses with EVA infection present with fever, anorexia, and depression. The clinical signs of respiratory infection due to EVA are serous nasal discharge, cough, conjunctivitis, lacrimation, and palpebral, scrotal, and periorbital edema. Clinical signs of disease persist for 2–9 days. Treatment consists of supportive care (support bandages) and NSAIDs for fever and inflammation. Antimicrobial therapy is usually unnecessary. A carrier state occurs in most stallions after natural infection and is primarily responsible for persistence of the virus in the horse population through infectious seminal fluids. Vaccination (modified-live virus) is targeted toward prevention of venereal spread of EVA in breeding animals as opposed to prevention of respiratory disease (*see p 701*).

HENDRA VIRUS INFECTION

(Equine morbillivirus)

Hendra virus (HeV) is the prototype species of a new genus *Henipavirus* within the subfamily Paramyxovirinae and was first identified in Australia in 1994. The viral agent is endemic in specific species of fruit bats (also called flying foxes), and close contact with these bats is suspected to have facilitated transfer of the HeV to horses. Horses are infected by oronasal routes and excrete HeV in urine, saliva, and respiratory secretions.

There have been multiple, sporadic incidents of human and equine disease in Australia occurring in 1994, 1995, 1999, 2004, 2008, and 2009. The case fatality rate

in horses and people is high, with reports of 81 horses and 4 people succumbing to Hendra virus infection, including an equine veterinarian investigating an outbreak.

Very close contact is required to transmit the virus among horses and from horses to people, and the virus is not considered highly contagious. Equine veterinarians are considered at occupational risk of contracting HeV. Infected horses develop severe and often fatal respiratory disease, characterized by dyspnea, vascular endothelial damage, and pulmonary edema. Depression, anorexia, fever, respiratory difficulty, ataxia, tachycardia, and frothy, nasal discharge are common clinical signs. (See also p 707.) A commercial HeV vaccine for use in horses is available under a Minor Use Permit for release to veterinarians who have completed an online training program. Horses must have a microchip to be vaccinated, and the information must be entered into the HeV Vaccine National Online Registry. The vaccine consists of soluble forms of G glycoprotein of HeV; it does not contain modified or inactivated virus.

PLEUROPNEUMONIA

(Pleuritis, Pleurisy)

Pleuropneumonia is defined as infection of the lungs and pleural space. In most instances, pleural infection develops secondary to bacterial pneumonia or penetrating thoracic wounds. Spontaneous pleuritis (without accompanying pneumonia) is uncommon in horses. In the USA, ~70% of horses with pleural effusion have pleuropneumonia. The primary differential diagnoses for pleural effusion are neoplastic effusions, heart failure, and hydatidosis.

Etiology and Pathogenesis: Viral respiratory infection, long-distance transportation, general anesthesia, and strenuous exercise are common predisposing factors that impair pulmonary defense mechanisms, allowing secondary bacterial invasion. Head restraint results in bacterial contamination and multiplication within the lower respiratory tract within 12–24 hr and may be the single most important predisposing factor for development of pneumonia associated with long-distance transport. Race and sport horses are particularly at risk. Most horses with pleuropneumonia are athletic horses <5 yr old. Exercise-induced pulmonary hemorrhage may contribute to development of respiratory infection by providing a favorable environment for

bacterial replication. Acute pulmonary infarction can be the inciting event for equine pleuropneumonia.

Polymicrobial and mixed anaerobic-aerobic infections are common in horses with pleuropneumonia, with more than one organism isolated from transtracheal aspirates. The most common aerobic organisms are *Streptococcus equi*, *zoepidemicus*, *Escherichia coli*, *Actinobacillus* spp, *Klebsiella* spp, *Enterobacter* spp, *Staphylococcus aureus*, and *Pasteurella* spp. Anaerobic bacteria are isolated from 40%–70% of horses with pleuropneumonia; *Bacteroides* spp, *Clostridium* spp, *Peptostreptococcus* spp, and *Fusobacterium* spp are the most common. The etiology of pleural infection in horses is usually bacterial, although *Mycoplasma felis* and nocardial agents have been isolated from pleural effusions.

Clinical Findings and Lesions: Horses with pleuropneumonia present with fever, depression, lethargy, and inappetence. Clinical signs specific to pleuropneumonia include pleural pain (pleurodynia) evident as short strides, guarding, and flinching on percussion of the chest; shallow respiration; and endotoxemia. Horses with pleural pain have an anxious facial expression; stand with their elbows abducted; and are reluctant to move, cough, or lie down. Gait may be stiff or stilted, and some horses grunt in response to thoracic pressure, auscultation, or percussion. Nasal discharge is a variable sign. Putrid breath or fetid nasal discharge indicates anaerobic bacterial infection and necrotic pulmonary tissue. The respiratory pattern is characterized by rapid, shallow respiration due to pleural pain and restricted pulmonary expansion from pleural effusion. A plaque of sternal edema is seen in horses with a large volume of pleural effusion. Horses with toxemia have injected mucous membranes, delayed capillary refill time (>2 sec), and tachycardia. Auscultation reveals a lack of breath sounds in the ventral lung fields and abnormal lung sounds (often crackles) in dorsal lung fields. Cardiac sounds may be muffled or absent or may radiate over a wider area. Although uncommon, pleural friction rubs are most prominent at end-inspiration and early expiration and are detected after thoracic drainage.

Diagnosis: In horses with peracute pleuropneumonia, laboratory findings reflect bacterial sepsis or toxemia and include abnormalities such as leukopenia,

neutropenia, left shift, hemoconcentration, and azotemia. Horses with more stable disease have leukocytosis, mature neutrophilia, hyperfibrinogenemia, hyperglobulinemia (chronic antigenic stimulation), hypoalbuminemia (loss in pleural space), and anemia of chronic disease.

Thoracic ultrasonography is ideal for investigation of pleural effusion and is indicated in horses with regions of poor to absent breath sounds, thoracic pain, and/or dull thoracic percussion. Transudative pleural fluid (neoplastic effusion) appears anechoic, whereas more cellular exudate appears echogenic. Gas echoes represent small air bubbles within pleural fluid, which may indicate an anaerobic pleural infection, a bronchopleural fistula, or iatrogenic introduction of air. Pulmonary atelectasis, consolidation, and abscessation can be identified if the lesions are located in peripheral lung fields. Ultrasonographic evidence of a large area of pulmonary consolidation, in conjunction with serosanguineous suppurative pleural effusion, is consistent with pulmonary infarction and necrotizing pneumonia. Adhesions of the visceral to parietal pleura can be visualized using thoracic ultrasonography, and these regions should be avoided during thoracocentesis.

Ultrasonography should be performed before pleurocentesis to determine the best site for maximal drainage and to avoid cardiac or diaphragmatic puncture. Thoracocentesis is performed for diagnostic and therapeutic purposes in horses with pleuropneumonia. Pleural fluid should be drained relatively slowly to avoid hypotension. The hemithorax that appears to contain the most fluid is drained first. Bilateral thoracocentesis is usually necessary. The chest tube may be removed immediately after drainage of the thoracic cavity or may be secured in place to allow continual drainage. Thoracic radiography is indicated after pleurocentesis to evaluate pulmonary parenchymal lesions, mediastinal structures, and the presence/severity of pneumothorax.

Gross examination of pleural fluid includes evaluation of color, odor, volume, and turbidity. Malodorous pleural fluid is associated with necrotic tissue and anaerobic infection and indicates a guarded prognosis. Cytologic evaluation of septic pleural fluid reveals purulent exudate (>90% neutrophils) with increased cellularity (25,000–200,000 cells/ μ L) and increased total protein (>3 g/dL). Intracellular and extracellular bacteria may be seen, and Gram stain examination is used to direct

initial antimicrobial therapy. Bacterial culture and sensitivity should also be performed on transtracheal aspirate samples, which yield positive bacterial cultures more frequently than pleural fluid samples.

Treatment: Management of horses with pleuropneumonia includes daily ultrasound examination to monitor fluid production, evaluate effective drainage, identify isolated fluid pockets, and assess peripheral pulmonary disease. The volume and character of pleural fluid will determine whether single, intermittent, or continual drainage is indicated. Continual drainage is preferable in cases with fibrinous, cellular, malodorous, and/or large volume of effusion. A one-way (Heimlich) valve allows constant drainage of pleural fluid with minimal risk of development of pneumothorax. An indwelling chest tube should remain in place as long as drainage is productive. Medical therapy includes broad-spectrum antibiotics, NSAIDs, analgesics, and supportive care. Broad-spectrum antimicrobial therapy targeting common aerobic and anaerobic bacteria (eg, penicillin, gentamicin, metronidazole) should be instituted pending results of culture and sensitivity. Intrathoracic fibrinolytic therapy has been reported to reduce fibrin deposition and pleural fluid accumulation. In some horses, the pleural infection does not resolve despite weeks to months of antimicrobial therapy and drainage via indwelling chest tubes. Thoracostomy allows manual removal of organized fibrinous material and necrotic lung; however, this technique should be limited to horses with chronic, stable, unilateral disease with resolving infection in the contralateral hemithorax.

Complications associated with pleuropneumonia include thrombophlebitis, laminitis, bronchopleural fistula, pulmonary abscess, and cranial thoracic mass.

The prognosis for horses with pleuropneumonia has greatly improved throughout the past 20 yr because of early recognition, advancements in diagnostic testing, and aggressive therapy. The survival rate is reported to be as high as 90% by some investigators, with a 60% chance of return to athletic performance. The duration of hospitalization is not indicative of outcome; however, a delay in initiation of appropriate therapy by >48 hr promotes development of anaerobic infection and, ultimately, poor response to treatment. Placement of an indwelling chest tube does not limit the prognosis for return to athletic function.

Horses with hemorrhagic necrotizing pneumonia respond poorly to conventional therapy and have a low survival rate.

RHODOCOCCLUS EQUI PNEUMONIA

Rhodococcus equi is the most serious cause of pneumonia in foals 1–4 mo old. It is not the most common cause of pneumonia in this age group; however, it has significant economic consequences because of mortality, prolonged treatment, surveillance programs for early detection, and relatively expensive prophylactic strategies. Clinical disease is rare in horses >8 mo old. Compelling epidemiologic data indicate pulmonary infection probably originates within the first week of life. (See also p 679.)

Etiology and Pathogenesis: *R equi* is a gram-positive, facultative intracellular pathogen that is nearly ubiquitous in soil. Inhalation of dust particles laden with virulent *R equi* is the major route of pneumonic infection. Development of clinical disease is related to immunocompetency of individual foals; foals that produce little to no detectable γ interferon (IFN- γ) are at risk of developing pneumonia. Manure from pneumonic foals is a major source of virulent bacteria contaminating the environment. Foals with pulmonary infections swallow sputum laden with *R equi*, which readily replicates in their intestinal tract. The pathogenicity of *R equi* is linked to its ability to survive intracellularly, which hinges on failure of phagosome-lysosomal fusion in infected macrophages and failure of functional respiratory burst upon phagocytosis of *R equi*.

Clinical Findings and Lesions: *R equi* infection is slowly progressive, with acute to subacute clinical manifestations. Clinical signs of disease are difficult to detect until pulmonary infection reaches a critical mass, resulting in decompensation of the foal. Pulmonary lesions are relatively consistent and include subacute to chronic suppurative bronchopneumonia, pulmonary abscessation, and suppurative lymphadenitis. At the onset of clinical signs, most foals are lethargic, febrile, and tachypneic. Diarrhea is seen in one-third of foals with *R equi* pneumonia and may be caused by colonic microabscessation. Cough is a variable clinical sign; purulent nasal discharge is less common. Thoracic auscultation reveals crackles and wheezes with asymmetric/regional distribution.

Pulmonary regions with marked consolidation lack breath sounds and exhibit dull resonance on thoracic percussion. In foals with subclinical infections, small to moderate-sized abscesses (<10 cm) may resolve spontaneously.

Immune-mediated polysynovitis (eg, stifle and hock effusion) is often seen in affected foals at presentation. Intestinal and mesenteric abscesses are the most common extrapulmonary sites of infection. Foals with abdominal involvement often present with fever, depression, anorexia, weight loss, colic, and diarrhea. Intestinal lesions are characterized by multifocal, ulcerative enterocolitis and typhlitis involving Peyer's patches with granulomatous or suppurative inflammation of the mesenteric and/or colonic lymph nodes. The prognosis for foals with abdominal forms of *R equi* is less favorable than for those with pulmonary disease. Septic phylitis and osteomyelitis are less common extrapulmonary sites of infection. Vertebral osteomyelitis may result in pathologic vertebral fracture and spinal cord compression and is a devastating manifestation of *R equi* osteomyelitis. Panophthalmitis, guttural pouch empyema, sinusitis, pericarditis, nephritis, nonseptic uveitis, and hepatic and renal abscessation with *R equi* have been reported.

Diagnosis: Routine laboratory evaluation of CBC and serum chemistry reveals nonspecific abnormalities consistent with infection and inflammation. Neutrophilic leukocytosis and hyperfibrinogenemia are common, and the severity of these findings relates to prognosis. Thoracic radiographic evaluation may reveal a pattern of perihilar alveolization, consolidation, and abscessation. The presence of nodular lung lesions and mediastinal lymphadenopathy in foals 1–4 mo old is highly suggestive of *R equi*. Bacterial culture of transtracheal wash samples is required for definitive diagnosis. Cytologic evaluation of transtracheal wash samples reveals intracellular coccobacilli, indicating that appropriate antimicrobial therapy should be started pending culture results.

Treatment and Prognosis: The combination of erythromycin (25 mg/kg, PO, qid; esters or salts) and rifampin (5–10 mg/kg, PO, bid) has historically been the treatment of choice for *R equi* infection in foals. These antimicrobials may be bacteriostatic, but their activity is synergistic, and the combination has markedly improved survival of foals with *R equi* pneumonia. Rifampin is lipid soluble (able

to penetrate abscess material) and is concentrated in phagocytic cells. Erythromycin is concentrated in granulocytes and alveolar macrophages; however, its antimicrobial activity is somewhat inhibited by intracellular pH. Adverse reactions are relatively common in foals treated with the erythromycin-rifampin combination. Diarrhea, idiosyncratic hyperthermia, tachypnea, anorexia, bruxism, and salivation can occur with erythromycin administration, and antimicrobial resistance of *R equi* to erythromycin-rifampin has been reported.

Clarithromycin is the macrolide of choice for foals with severe disease, given the most favorable minimum inhibitory concentration against *R equi* isolates obtained from pneumonic foals (90% of isolates are inhibited at 0.12, 0.25, and 1 mcg/mL for clarithromycin, erythromycin, and azithromycin, respectively). In foals with *R equi* pneumonia, the combination of clarithromycin (7.5 mg/kg, PO, bid) and rifampin is superior to erythromycin-rifampin and azithromycin-rifampin. Foals treated with clarithromycin-rifampin have improved survival rates and fewer febrile days than foals treated with erythromycin-rifampin and azithromycin-rifampin. Reported adverse events of clarithromycin-rifampin include diarrhea in treated foals. The duration of antimicrobial therapy typically is 3–8 wk.

Supportive therapy includes provision of a clean, comfortable environment and highly palatable, dust-free feeds. Judicial IV fluid therapy and saline nebulization facilitates expectoration of pulmonary exudates. NSAIDs should be administered as needed to maintain rectal temperature <103.5°F (39.7°C). Nasal insufflation with oxygen is necessary in foals with severe respiratory compromise. Bronchodilator therapy may or may not improve arterial oxygenation. Prophylactic antulcer medication is indicated in foals stressed by respiratory difficulty, pain, frequent handling, hospitalization, and transportation.

The survival rate of *R equi* pneumonia is ~70%–90% with appropriate therapy. The case fatality rate without therapy (or with inappropriate antimicrobial therapy) is ~80%. Parameters for discontinuation of medical therapy include clinical signs, serum fibrinogen concentration, and radiographic resolution of pulmonary consolidation and abscessation. Life-threatening, antibiotic-induced enterocolitis, due to *Clostridium difficile*, has been seen in the dams of nursing foals treated with all macrolide preparations.

Prevention: There are several strategies to decrease the incidence of *R equi* pneumonia on endemic farms: early detection of clinical cases, enhanced passive immunity for neonatal foals, and enhanced nonspecific immunity for neonatal foals. Foals should be maintained in well-ventilated, dust-free areas, avoiding dirt paddocks and overcrowding. Pneumonic foals should be isolated and their manure composted. Herd surveillance programs for early detection of pneumonic foals on endemic farms include twice weekly physical examination and auscultation and monthly CBC and fibrinogen concentration. Foals with a WBC count >14,000 cells/ μ L should be further evaluated via ultrasonographic examination for *R equi*. Administration of hyperimmune plasma might reduce the incidence and severity of *R equi* within the herd, but it is not completely effective in preventing disease. Hyperimmune plasma (1 L) is administered IV within the first week of life, followed by a second liter at ~25 days of age. Foals with low IFN- γ production in the first month of life appear more susceptible to development of clinical disease. Administration of a nonspecific immunostimulant may enhance IFN- γ production and protect this susceptible population. Mass treatment of foals with subclinical infection has resulted in marcolide- and rifampin-resistant strains and should be avoided.

ACUTE BRONCHOINTERSTITIAL PNEUMONIA IN FOALS

Acute bronchointerstitial pneumonia is a sporadic, rapidly progressive disease of foals characterized by acute respiratory distress and high mortality.

Etiology, Epidemiology, and Pathogenesis: The etiology of acute bronchointerstitial pneumonia in foals is not clear. It may result from different insults rather than a single factor, initiate a cascade of events, and result in a final common response of severe pulmonary damage and acute respiratory distress. Warm weather (>85°F [29.4°C]) is a common epidemiologic factor. Many foals have a history of antimicrobial therapy when clinical signs developed. No virus is consistently isolated, and no bacterial agent has been consistently identified. Enteric gram-negative organisms, *Rhodococcus equi*, *Pseudomonas aeruginosa*, and *Pneumocystis jiroveci* have been cultured from the lungs of affected foals.

Clinical Findings and Lesions: The age of affected foals ranges from 1 wk to 8 mo. Acute bronchointerstitial pneumonia has an acute or peracute onset and is accompanied by high fever. The disease is rapidly progressive and may result in sudden death due to fulminant respiratory failure. Foals are unable or reluctant to move and are usually cyanotic. Severe respiratory distress is the most striking clinical sign. Clinicopathologic evaluation of foals with acute respiratory distress should include arterial blood gas, CBC, serum chemistry analysis, and thoracic radiographs. Hypoxemia, hypercapnea, and respiratory acidosis are consistent findings. These arterial blood gas findings quantify the severity of respiratory impairment and are used to monitor response to therapy. The hypoxemia of bronchointerstitial pneumonia is relatively resistant to supplemental oxygen therapy. Bronchointerstitial pneumonia is similar to bacterial pneumonia in that hyperfibrinogenemia and neutrophilic leukocytosis are seen in most foals.

Diagnosis: Physical examination and clinicopathologic findings may appear similar to those of foals with severe *R equi* pneumonia (see p 1451), and thoracic radiographic examination may be the most valuable diagnostic test to differentiate *R equi* pneumonia from bronchointerstitial pneumonia. Interstitial pneumonia appears as diffuse to caudodorsally distributed interstitial and bronchointerstitial pulmonary opacities. With advanced disease, the radiographic pattern progresses to include patches of a coalescing alveolar nodular pattern with air bronchograms. Transtracheal aspiration may be prohibitively dangerous to perform on a dyspneic foal but should be done when the foal becomes more stable to obtain samples for bacterial culture/sensitivity, cytologic evaluation, and virus isolation. Cytologic evaluation of tracheal aspirates reveals acute neutrophilic inflammation with or without evidence of sepsis. Bacterial organisms are often recovered from transtracheal aspiration samples or necropsy of foals with bronchointerstitial pneumonia; however, no single organism is consistently recovered.

Necropsy examination reveals diffusely enlarged lungs that fail to deflate upon opening of the thoracic cavity with rib impressions on the visceral pleural surface. The cut surface of lung is mottled, with dark red lung interspersed with more normal-appearing lung tissue and edematous separation of lobules. The most prominent histopathologic findings are severe, diffuse,

necrotizing bronchiolitis, alveolar septal necrosis, and neutrophilic alveolitis. Surviving foals develop a proliferative epithelial and interstitial response, including bronchiolar and alveolar epithelial hyperplasia, type II cell hyperplasia, and hyaline membrane formation.

Treatment: Because the cause of bronchointerstitial pneumonia is unknown, therapy is symptomatic. Treatment includes anti-inflammatory therapy, broad-spectrum antibiotics, thermoregulatory control, bronchodilation, supplemental oxygen, and supportive care. Anti-inflammatory therapy with corticosteroids (eg, dexamethasone 0.1 mg/kg/day, IV) appears to improve survival. An alcohol bath, an air-conditioned stall, and/or a fan are used in conjunction with NSAIDs to maintain rectal temperature <103.5°F (39.7°C). The suitability of an antibiotic regimen appears to have little bearing on the outcome of bronchointerstitial pneumonia. Nonetheless, broad-spectrum antibiotic therapy should be instituted to treat existing or impending secondary bacterial infections. Additional supportive therapy includes provision of a clean, comfortable environment; highly palatable, dust-free feeds; and ulcer prophylaxis.

Prognosis: Although mortality is high, affected foals that receive aggressive medical care have a reasonably favorable prognosis for survival (70%). The longterm pulmonary consequences after recovery from bronchointerstitial pneumonia are variable, ranging from undetectable to persistent exercise intolerance.

STRANGLES

(Distemper)

Strangles is an infectious, contagious disease of Equidae characterized by abscessation of the lymphoid tissue of the upper respiratory tract. The causative organism, *Streptococcus equi equi*, is highly host-adapted and produces clinical disease only in horses, donkeys, and mules. It is a gram-positive, capsulated β -hemolytic Lancefield group C coccus, which is an obligate parasite and a primary pathogen.

Etiology and Pathogenesis: *S equi equi* is highly contagious and produces high morbidity and low mortality in susceptible populations. Transmission occurs via fomites and direct contact with infectious exudates. Carrier animals are important for

Strangles. Courtesy of Dr. Thomas Lane.

maintenance of the bacteria between epizootics and initiation of outbreaks on premises previously free of disease. Survival of the organism in the environment depends on temperature and humidity; it is susceptible to desiccation, extreme heat, and exposure to sunlight and must be protected within mucoid secretions to survive. Under ideal environmental circumstances, the organism can survive ~4 wk outside the host. Under field conditions, most organisms do not survive 96 hr.

Clinical Findings: The incubation period of strangles is 3–14 days, and the first sign of infection is fever (103°–106°F [39.4°–41.1°C]). Within 24–48 hr of the initial fever spike, the horse will exhibit signs typical of strangles, including mucoid to mucopurulent nasal discharge, depression, and submandibular lymphadenopathy. Horses with retropharyngeal lymph node involvement have difficulty swallowing, inspiratory respiratory noise (compression of the dorsal pharyngeal wall), and extended head and neck. Older animals with residual immunity may develop an atypical or catarrhal form of the disease with mucoid nasal discharge, cough, and mild fever. Metastatic strangles (“bastard strangles”) is characterized by abscessation in other lymph nodes of the body, particularly the lymph nodes in the abdomen and, less frequently, the thorax. *S. equi* is the most common cause of brain abscess in horses, albeit rare.

Diagnosis: Diagnosis is confirmed by bacterial culture of exudate from abscesses or nasal swab samples. CBC reveals neutrophilic leukocytosis and hyperfibrinogenemia. Serum biochemical analysis is typically unremarkable. Complicated cases may require endoscopic examination of the upper respiratory tract (including the guttural pouches), ultrasonographic

examination of the retropharyngeal area, or radiographic examination of the skull to identify the location and extent of retropharyngeal abscesses.

Treatment: The environment for clinically ill horses should be warm, dry, and dust-free. Warm compresses are applied to sites of lymphadenopathy to facilitate maturation of abscesses. Facilitated drainage of mature abscesses will speed recovery. Ruptured abscesses should be flushed with dilute (3%–5%) povidone-iodine solution for several days until discharge ceases. NSAIDs can be administered judiciously to reduce pain and fever and to improve appetite in horses with fulminant clinical disease. Tracheotomy may be required in horses with retropharyngeal abscessation and pharyngeal compression.

Antimicrobial therapy is controversial. Initiation of antibiotic therapy after abscess formation may provide temporary clinical improvement in fever and depression, but it ultimately prolongs the course of disease by delaying maturation of abscesses. Antibiotic therapy is indicated in cases with dyspnea, dysphagia, prolonged high fever, and severe lethargy/anorexia. Administration of penicillin during the early stage of infection (≤ 24 hr of onset of fever) will usually arrest abscess formation. The disadvantage of early antimicrobial treatment is failure to mount a protective immune response, rendering horses susceptible to infection after cessation of therapy. If antimicrobial therapy is indicated, procaine penicillin (22,000 IU/kg, IM, bid) is the antibiotic of choice. Untreated guttural pouch empyema with or without chondroid formation.

Prevention: Postexposure immunity is prolonged after natural disease in most horses, and protection is associated with local (nasal mucosa) production of antibody against the antiphagocytic M protein. The clinical attack rate of strangles is reduced by 50% in horses vaccinated with IM products that do not induce mucosal immunity. Local (mucosal) production of antibody requires mucosal antigen stimulation. An intranasal vaccine containing a live attenuated strain of *S. equi equi* was designed to elicit a mucosal immunologic response. This attenuated strain is not temperature sensitive (inactivated by core body temperature) like the intranasal influenza vaccine. Reported complications include *S. equi equi* abscesses at subsequent IM injection

sites (live bacteria on hands of administrator), submandibular lymphadenopathy, serous nasal discharge, and purpura hemorrhagica (see p 828).

Control: Clinically affected horses should be physically separated from the herd and cared for by separate caretakers wearing protective clothing. The rectal temperature of all horses exposed to strangles should be obtained twice daily, and horses developing fever should be isolated (and potentially treated with penicillin). Contaminated equipment should be cleaned with detergent and disinfected using chlorhexidine gluconate or glutaraldehyde. Flies can transmit infection mechanically; therefore, efforts should be made to control the fly population during an outbreak. Farriers, trainers, and veterinarians should wear protective clothing or change clothes before traveling to the next equine facility. Additions to the herd should be carefully scrutinized for evidence of disease or shedding (nasopharyngeal culture) and quarantined for 14–21 days. Two negative nasal swab cultures should be obtained during the quarantine period.

Most horses continue to shed *S equi* for ~1 mo after recovery. Three negative nasopharyngeal swabs, at intervals of 4–7 days, should be obtained before release from quarantine, and the minimal isolation period should be 1 mo. Prolonged bacterial shedding (as long as 18 mo) has been identified in a small number of horses. Guttural pouch empyema is the source of infection in most prolonged carrier states. Bacterial culture of nasopharyngeal swab and/or guttural pouch lavage is used to identify persistent carriers.

RECURRENT AIRWAY OBSTRUCTION

(Heaves, Chronic obstructive pulmonary disease)

Recurrent airway obstruction (RAO) is a common, performance-limiting, allergic respiratory disease of horses characterized by chronic cough, nasal discharge, and respiratory difficulty. Episodes of airway obstruction are seen when susceptible horses are exposed to common allergens. Most horses exhibit clinical signs when stabled, bedded on straw, and fed hay, whereas elimination of these inciting factors results in remission or attenuation of clinical signs.

The pathophysiology involves small-airway inflammation (neutrophilic), mucus production, and bronchoconstriction in response to allergen exposure.

Etiology: The average age at onset is 9 yr. Approximately 12% of mature horses have some degree of allergen-induced lower airway inflammation. There is no breed or gender predilection; however, there does appear to be a heritable component to susceptibility.

Clinical Findings: Horses present with flared nostrils, tachypnea, cough, and a heave line. The typical breathing pattern is characterized by a prolonged, labored expiratory phase of respiration. Cough may be productive and often occurs during feeding or exercise. The abdominal muscles respond by assisting with expiration, and hypertrophy of these muscles produces the classic heave line. Characteristic auscultatory findings include a prolonged expiratory phase of respiration, wheezes, tracheal rattle, and overexpanded lung fields. Wheezes are generated by airflow through narrowed airways and are most pronounced during expiration. Crackles may be present and are associated with excessive mucus production. Mild to moderately affected horses may present with minimal clinical signs at rest, but coughing and exercise intolerance are noted during performance. Horses with RAO are not typically febrile unless secondary bacterial pneumonia has developed.

Horses from the southeastern USA may demonstrate clinical signs on late-summer pasture, which likely reflects sensitivity to molds or grass pollens. This is referred to as **summer pasture-associated obstructive**

Chronic obstructive pulmonary disease with "heave line" along the costal arch. Courtesy of Dr. Thomas Lane.

pulmonary disease. The management is similar to that of a horse with heaves, with the addition of pasture avoidance.

Diagnosis: The diagnosis of RAO is determined in most horses on the basis of history and characteristic physical examination findings. Hematology and serum chemistry results are unremarkable. Radiographic findings in horses with RAO are peribronchial infiltration and overexpanded pulmonary fields (flattening of the diaphragm). Thoracic radiographs are of little benefit in confirming the diagnosis of RAO and may not be necessary in horses with characteristic clinical signs, unless there is no response to standard treatment after 14 days of therapy. However, they may help identify the most important differential diagnoses, including interstitial pneumonia, pulmonary fibrosis, or bacterial pneumonia.

Bronchoalveolar lavage is rarely required for diagnosis of fulminant RAO and is not innocuous in horses that are dyspneic at rest. It is indicated in horses with mild to moderate disease with poor performance and coughing during exercise. Neutrophilic inflammation (20%–90% of total cell count) confirms the presence of lower airway inflammation and differentiates horses with eosinophilic pneumonitis, fungal pneumonia, or lungworm infestation from horses with heaves. Curschmann spirals may be seen on cytologic evaluation and represent inspissated mucus/cellular casts from obstructed small airways.

Treatment: The single most important treatment is environmental management to reduce allergen exposure. Medication will alleviate clinical signs of disease; however, respiratory disease will return after medication is discontinued if the horse remains in the allergen-challenged environment. The most common culprits are organic dusts present in hay, which need not appear overtly musty to precipitate an episode in a sensitive horse. Horses should be maintained at pasture, with fresh grass as the source of roughage, supplemented with pelleted feed. Round bale hay is particularly allergenic and a common cause of treatment failure for horses on pasture. Horses that remain stalled should be maintained in a clean, controlled environment. Complete commercial feeds eliminate the need for roughage. Hay cubes and hay silage are

acceptable, low-allergen alternative sources of roughage and may be preferred by horses over the complete feeds.

Soaking hay with water before feeding may control clinical signs in mildly affected horses but is unacceptable for highly sensitive horses. Horses maintained in a stall should not be housed in the same building as an indoor arena, hay should not be stored overhead, and straw bedding should be avoided. Horses with summer pasture-associated obstructive pulmonary disease should be maintained in a dust-free, stable environment.

Medical treatment consists of a combination of bronchodilating agents (to provide relief of airway obstruction) and corticosteroid preparations (to reduce pulmonary inflammation). Bronchodilator therapy (β agonists and parasymphatholytic agents) will provide immediate relief of airway obstruction until clinical signs of disease are controlled by corticosteroids. Severely affected horses are ideally controlled with aerosolized bronchodilators (eg, albuterol, ipratropium) and systemic corticosteroids (eg, dexamethasone 0.1 mg/kg/day, IV). Horses with mild to moderate airway inflammation can be treated with aerosolized corticosteroids and aerosolized or systemic (clenbuterol) bronchodilators. It is inappropriate to treat RAO with bronchodilators as the sole therapy. NSAIDs, antihistamines, and leukotriene-receptor antagonists have not demonstrated therapeutic benefit.

INFLAMMATORY AIRWAY DISEASE

(Lower respiratory tract inflammation, Small airway inflammatory disease)

Inflammatory airway disease (IAD) describes a heterogeneous group of inflammatory conditions of the lower respiratory tract that appear to be primarily noninfectious. IAD occurs in 22%–50% of athletic horses and is a common cause of impaired performance and interruption of training.

Etiology and Pathophysiology:

Proposed etiologies of IAD include allergic airway disease, recurrent pulmonary stress, deep inhalation of dust, atmospheric pollutants, and/or persistent respiratory viral infections, most notably EHV-2. IAD often develops after an overt viral respiratory infection and may result from inability of the immune system to fully eliminate viruses or bacteria from small airways. *Streptococcus pneumoniae* has been

isolated from horses with IAD; however, its role in the pathophysiology is unclear, because this population of horses is largely unresponsive (or transiently responsive) to antibiotic therapy.

Clinical Findings: The most common clinical signs are chronic cough and mucoid to mucopurulent nasal discharge. Fever and auscultable pulmonary abnormalities are rarely seen. Horses with IAD demonstrate poor exercise tolerance at maximal speed. Endoscopic examination reveals mucopurulent exudate in the pharynx, trachea, and bronchi.

Diagnosis: Diagnosis of IAD is based on poor race performance and clinical signs. Bronchoalveolar lavage is performed to characterize the type of pulmonary inflammation. Cytologic evaluation of bronchoalveolar fluid will reveal one of the following inflammatory profiles: 1) mixed inflammation with high total nucleated cells, mild neutrophilia (15% of total cells), lymphocytosis, and monocytosis; 2) increased metachromatic cells (mast cells >2% of total cells); or 3) eosinophilic inflammation (5%–40% of total cells). The mixed inflammatory profile likely results from environmental irritation or the consequences of a previous infectious disease.

Treatment: The type of inflammation in bronchoalveolar fluid will dictate the therapeutic plan. Regardless of the cytologic profile, all horses with IAD should receive aerosolized bronchodilator therapy before exercise to avert exercise- or irritant-induced bronchoconstriction. In horses with a mixed inflammatory cytologic profile, administration of low-dose interferon- α is recommended for immunomodulation and antiviral activity. Interferon- α reduces tracheal exudate and improves cytologic profiles in horses with mixed inflammatory IAD. Eosinophilic bronchoalveolar fluid likely represents a Type I hypersensitivity reaction. In addition to tracheal exudates, peripheral eosinophilia, miliary pulmonary opacities, and eosinophilic pulmonary granulomas may be seen in affected horses. If such fluid is identified, parasitic pulmonary disease should be considered in addition to hypersensitivity pneumonitis. Systemic corticosteroid therapy is recommended to reduce pulmonary inflammation in horses with eosinophilic IAD. Mast cell inflammation likely represents a local pulmonary hypersensi-

tivity response and may represent an early form of recurrent airway obstruction (*see p 1455*). In IAD-affected horses with increased mast cells in bronchoalveolar fluid, aerosol administration of an inhaled corticosteroid preparation (beclomethasone or fluticasone) improves clinical signs of respiratory disease.

EXERCISE-INDUCED PULMONARY HEMORRHAGE

(Epistaxis, "Bleeder")

Exercise-induced pulmonary hemorrhage (EIPH) is seen in most racehorses and in many other horses used in equine sports (eg, polo, barrel racing, 3-day events) that require strenuous exercise for short periods of time. Epistaxis is seen in a small proportion (~5%) of horses with EIPH. Blood in the tracheobronchial tree is identified in 45%–75% of racehorses via endoscopic examination, and hemorrhage is detected by cytologic examination of bronchoalveolar lavage in >90% of racehorses.

Etiology: The proposed pathophysiologic mechanism for pulmonary hemorrhage includes high pulmonary vascular pressures during maximal exercise, with resultant thickening of pulmonary vein walls and decreased luminal diameter and increased intravascular pressure at the level of the pulmonary capillaries.

Diagnosis: Endoscopic observation of blood in the airways 30–90 min after exercise provides definitive evidence of EIPH. Other sources of hemorrhage in the upper airway, particularly guttural pouch mycosis (*see p 1463*) and ethmoid hematoma (*see p 1462*), must be excluded during endoscopic examination. If EIPH is suspected and the horse cannot be examined after exercise, cytologic examination of bronchoalveolar lavage fluid for semiquantitative assessment of hemosiderophages is diagnostic. Stains that highlight iron-containing pigments (Prussian blue) facilitate recognition of these cells. Thoracic radiography demonstrates alveolar or mixed alveolar-interstitial opacities in the caudodorsal lung fields; however, radiographic examination of the thorax has little impact on the diagnosis or management of EIPH.

Treatment and Control: Furosemide reduces the incidence and severity of

EIPH in Thoroughbred racehorses. Horses with and without EIPH demonstrate equal improvements in race performance after administration of furosemide, indicating that the drug may enhance performance via mechanisms unrelated to EIPH. Application of nasal dilator bands reduces RBC counts in bronchoalveolar fluid from affected horses running on a treadmill by 33%. Alternative treatments, including procoagulant agents (eg, vitamin K, conjugated estrogens, aminocaproic acid), antihypertensive drugs, rheologic agents (pentoxifylline), bronchodilators, prolonged rest, dietary supplements (hesperidin-citrus bioflavonoids), and anti-inflammatory drugs, have not demonstrated therapeutic benefit.

LARYNGEAL HEMIPLEGIA

(Roaring, Left laryngeal hemiplegia)

Left recurrent laryngeal hemiplegia is characterized by paresis or paralysis of the left arytenoid cartilage and vocal fold. It manifests clinically as exercise intolerance and inspiratory respiratory noise ("roaring") during exercise. Right-sided hemiplegia and bilateral (paraplegia) arytenoid dysfunction are uncommon.

Etiology and Pathogenesis: Progressive loss of the large myelinated fibers in the distal portion of the recurrent laryngeal nerves results in neurogenic atrophy of the intrinsic laryngeal musculature, the most crucial of which is the cricoarytenoideus dorsalis muscle. Axonal dystrophy of the left recurrent nerve occurs more commonly than the right, perhaps due to its extended length around the base of the heart. Left laryngeal hemiplegia is likely heritable. Less common causes include direct trauma to the recurrent laryngeal nerve, accidental perivascular injection of irritating substances, and plant (eg, *Cicer arietinum* [chick peas] and *Lathyrus* spp) and chemical intoxications. Lead toxicity should be suspected in horses with bilateral laryngeal paralysis. The peroneal nerve (similar length to the left recurrent laryngeal) may be affected with toxic insults, and axonal dystrophy of the peroneal nerve may manifest as stringhalt (see p 1137). Although all breeds are affected, prevalence is higher in males and long-necked/larger breeds. The prevalence in young Thoroughbreds presented for sale is estimated to be ~3%–5%.

Loss of neuromuscular control of the abductor muscle results in collapse of the arytenoid cartilage and vocal fold, which reduces the glottal cross-sectional area. The resistance to airflow necessitates greater respiratory effort. Because of the pliable nature of the glottis, the exaggerated subatmospheric pressure in the airway results in further collapse of the arytenoid cartilage and exacerbation of the impedance to airflow. Upon inspiration during strenuous exercise, the affected side is drawn across the midline (by negative pressure in the airway) until it abuts the abducted normal arytenoid, effectively occluding the airway (dynamic collapse). The characteristic inspiratory whistle results from resonance within the open ventricle on the affected side. The harsher stridor, or roar, is produced by vortex shedding from the edges of the arytenoid cartilage and vocal fold.

Clinical Findings and Diagnosis: The principal clinical signs are inspiratory noise during exercise and exercise intolerance. Affected horses are asymptomatic at rest but may have an unusual whinny. Diagnosis is confirmed by endoscopic observation of reduced or absent mobility of the arytenoid cartilage and vocal fold. With laryngeal hemiplegia, the arytenoid cartilage and vocal fold are located in a median position within the laryngeal lumen and are immobile. Asynchronous movements of the laryngeal cartilages occur commonly, with variable clinical relevance. Horses with laryngeal asynchrony, exercise intolerance, and respiratory noise during exercise should have their laryngeal function evaluated endoscopically during treadmill exercise to confirm laryngeal dysfunction.

Differential diagnoses include other pharyngeal conditions that produce upper

Endoscopic image demonstrating grade IV paralysis of the left arytenoid from a horse with left laryngeal hemiplegia at rest. Courtesy of Dr. Bonnie R. Rush.

airway obstruction and exercise intolerance. Most of these conditions are easily differentiated from laryngeal hemiplegia during endoscopic examination. Although arytenoid chondritis may be confused with laryngeal hemiplegia, misdiagnosis can be avoided by observation of the shape and size of the arytenoid cartilages. In arytenoid chondritis, the arytenoids thicken transversely and lose their characteristic "bean" shape. Abduction and adduction are usually limited. The axial (medial) surface of the arytenoid cartilage may be distorted with granulation tissue protruding through the mucosa, and a contact (kissing) lesion may be present on the contralateral arytenoid cartilage. Arytenoid chondritis should always be considered if motility of the right arytenoid is reduced. Radiographic examination of the pharynx may reveal mineralization within the arytenoid cartilages in cases of chondritis.

Treatment: Prosthetic laryngoplasty can stabilize the affected side of the larynx during inspiration and prevent dynamic collapse of the airway during exercise. Laryngeal ventriculectomy performed via laryngotomy, or ventriculocordectomy performed via transendoscopic laser, improves airflow and reduces the "roaring" sound during exercise. Prosthetic laryngoplasty is commonly done in racing horses and is the only technique that satisfactorily reduces the impedance to inspiratory flow. Postoperative complications include chronic cough, chronic aspiration of feed, implant failure, and implant infection. Athletic performance will improve after surgery; however, horses are more likely to experience inflammatory airway disease and exercise-induced pulmonary hemorrhage, have fewer race starts, and are unlikely to develop their predicted performance potential.

PHARYNGEAL LYMPHOID HYPERPLASIA

(Pharyngitis)

Pharyngeal lymphoid hyperplasia is a common condition of the dorsal pharyngeal wall seen in young horses (1–3 yr old). Horses do not have discrete masses of lymphoid tonsillar tissue; rather, they have many small foci or follicles of lymphoid tissue spread diffusely over the roof and lateral walls of the pharynx. In mature horses, these follicles blend with mucosal

Endoscopic photograph of grade 3.5/4 pharyngeal lymphoid hyperplasia. Courtesy of Dr. Jan Hawkins.

tissue and are unnoticeable. In young, maturing horses, lymphoid follicles appear as prominent, raised nodules on the surface of the pharyngeal roof and extend down the lateral walls of the pharynx and cranially into the nasopharynx. Although PLH was once believed to be an important cause of poor performance in racehorses, its clinical significance is now questionable. Virtually all young horses develop hyperplasia of pharyngeal lymphoid follicles; in most cases, this represents a normal immunologic event.

Occasionally, follicles may enlarge and coalesce with surrounding follicles. In these situations, follicles may appear hyperemic or inflamed and may exude mucoid or mucopurulent material. These cases likely represent a mild or subclinical viral infection and may be associated with impaired performance. Signs of pharyngeal pain include reduced appetite and frequent swallowing. Treatment is not necessary in the vast majority of cases; however, rest and NSAID administration are warranted in horses demonstrating pharyngeal pain.

DORSAL DISPLACEMENT OF THE SOFT PALATE

Dorsal displacement of the soft palate (DDSP) is a performance-limiting condition of the upper respiratory tract and is a relatively common cause of upper respiratory noise during exercise. During DDSP, the caudal free margin of the soft palate moves dorsal to the epiglottis,

creating a functional obstruction within the airway. The cross-sectional area of the pharynx is reduced, and airflow resistance and turbulence are increased.

Etiology and Pathogenesis: DDSP may result from several pathophysiologic mechanisms. Inflammation of the upper respiratory tract due to infection may cause neuropathy of the pharyngeal branch of the vagus nerve as it traverses the floor of the medial compartment of the guttural pouch, resulting in neuromuscular dysfunction of the pharyngeal muscles that control the soft palate. The retropharyngeal lymph nodes are in direct contact with the pharyngeal branch of the vagus nerve, and retropharyngeal lymphadenopathy may result in compression and irritation. Clinical signs can be induced by local anesthesia of this nerve. Congenital hypoplasia of the epiglottis may contribute to DDSP due to insufficient epiglottal tissue to maintain the position of the caudal border of the soft palate ventral to the epiglottis. Horses that have undergone laryngoplasty for left laryngeal hemiplegia are more likely to develop DDSP.

Clinical Findings: DDSP creates a characteristic gurgling respiratory noise, primarily during expiration, due to vibration of the soft palate. Horses may make no noise at the onset of exercise but displace their palate during high-speed exercise, causing them to "choke down." Head position (flexed) may contribute to displacement.

Treatment: The most effective treatment for DDSP in young horses (2-yr-olds) and horses with evidence of upper respiratory tract infection is rest and anti-inflammatory therapy. Caudal retraction of the tongue elevates the soft palate and pushes the larynx caudally, both of which may predispose to DDSP. Placing a tongue tie during exercise reduces caudal retraction of the tongue. Sternothyrohyoideus myectomy performed in horses prone to DDSP to alter the anatomy of the upper respiratory tract is successful in ~50% of horses. Soft palate resection (staphylectomy) is frequently performed in horses with DDSP and also has a success rate of ~50%; however, the mechanism of improvement after surgery is unclear. Success has been attributed to reduction in the mass of soft palate obstructing the airway, easier replacement of the shorter soft palate to the subepiglottic position, and firming of the

caudal edge of the soft palate to keep it ventral to the epiglottis. Palatal sclerotherapy via endoscopic-guided sodium tetradecylallyl sulfate injection has demonstrated success in a small number of horses, resolving respiratory noise in 7 of 8 horses and improving performance in 6 of 8 horses. A laryngeal tie-forward procedure can be performed to alter the position of the larynx with respect to the caudal edge of the soft palate.

EPIGLOTTIC ENTRAPMENT

Epiglottic entrapment is a less common cause of respiratory noise and exercise intolerance. In this condition, the aryepiglottic fold completely envelops the apex and lateral margins of the epiglottis. The general shape of the epiglottis is visible, and the position (dorsal to the soft palate) is appropriate. However, the distinct serrated margins of the epiglottis and the dorsal epiglottic vascular pattern are obscured by a fold of aryepiglottic mucosa. Clinical signs of epiglottic entrapment include inspiratory and expiratory respiratory noise during exercise and poor exercise performance. Less common signs include cough, nasal discharge, and headshaking. In mature nonracehorses, cough is the most consistent presenting complaint. Diagnosis is determined by endoscopic examination. Surgical correction of epiglottic entrapment is axial division of the aryepiglottic fold to free the epiglottis. Axial transection of the aryepiglottic fold may be performed by transendoscopic contact Nd:YAG laser, transnasal or transoral transection via curved bistoury, or direct excision through a laryngotomy or pharyngotomy. Surgical transection is generally curative, with a relapse rate of 5%. Some affected horses can race successfully with the condition.

SUBEPIGLOTTIC CYST

Subepiglottic cysts are an uncommon cause of respiratory noise in young horses. They are likely present from birth but remain undetected until the horse begins exercise training. These cysts are suspected to arise from remnants of the thyroglossal duct. Clinical signs include respiratory noise and exercise intolerance. Large cysts may produce coughing, dysphagia, and aspiration in foals. Diagnosis is determined by endoscopic examination of the upper respiratory tract. The cyst appears as a smooth-walled, fluctuant mass that contains

thick, yellow, mucoid material. Occasionally, the mass is not visible in the nasopharynx, and oral examination under general anesthesia may be required to identify it. Histologically, subepiglottic cysts are lined with a combination of stratified squamous and pseudostratified columnar epithelium. Treatment involves complete removal of the secretory lining of the cyst. Rupture of the cyst results in immediate decompression, but recurrence is common. The most common approach is ventral laryngotomy, although transendoscopic Nd:YAG laser surgery has been used for complete excision.

FOURTH BRANCHIAL ARCH DEFECT

(Rostral displacement of the palatopharyngeal arch)

The extrinsic structures of the larynx, such as the wing of the thyroid cartilage, cricothyroid muscle, and upper esophageal sphincter, develop from the fourth branchial arches. Aplasia or hypoplasia of one or more of these structures may occur unilaterally or bilaterally. Right-sided defects are more common than bilateral or left-sided defects. The severity of clinical manifestation ranges broadly and is based on the degree of the defect. The most common clinical sign is respiratory noise, although mild dysphagia, eructation, and cough have been reported. Palpation of the larynx reveals absence of one or both wings of the thyroid cartilage, resulting in failure of the cricothyroid articulation and a palpable space between the cricoid and thyroid cartilages. Radiographic evidence of a fourth branchial arch defect includes dilation of the cricopharynx with a continuous column of air from the pharynx to the cervical esophagus. Rostral displacement of the palatopharyngeal arch may or may not be detected during endoscopic examination. Endoscopic examination during treadmill exercise may reveal dynamic collapse of the vocal folds. Affected horses are unlikely to become effective athletes. Partial arytenoidectomy may improve airway dynamics sufficiently for pleasure riding.

DISEASES OF THE NASAL PASSAGES

Nasal Septum

Diseases of the nasal septum are rare. Most nasal septal disorders are congenital abnormalities that remain undetected until the horse is exercised. Traumatic injury to the

bridge of the nose as a juvenile can produce nasal septal deviation and thickening. Other less common diseases of the nasal septum include amyloidosis, fungal infection, and squamous cell carcinoma.

Thickening or deviation of the nasal septum causes low-pitched stertorous breathing during exercise. Facial deformity may be seen. Septal abnormalities may be detected by palpation, visual inspection, and endoscopic examination. Dimensions of the nasal cavity are difficult to appreciate via endoscopic examination; however, abnormalities of the mucosa are easily identified. Precise dorsoventral radiographs of the skull provide definitive evidence of septal deformity, deviation, and thickening. Histologic examination of any nodules or discrete lesions on the septum will identify tumors, amyloidosis, or fungal infections.

Surgical resection of the nasal septum is the only treatment option in most cases. The entire diseased portion of the septum can be excised using obstetrical wire by transecting the septum on the dorsal, ventral, and caudal border. Hemorrhage is substantial during this procedure (4–8 L), and the nasal passages are packed with sterile gauze soaked in saline or in 1:100,000 epinephrine solution to minimize blood loss. Before the horse recovers from anesthesia, a tracheotomy is performed.

Postoperative care includes parenteral antibiotics and NSAIDs. The packing and tracheotomy tube should be removed 48–72 hr after surgery. All incisions heal by second intention within 3 wk. Horses should be rested for ~2 mo before returning to normal activity. After surgery, most horses make a respiratory noise during work, although less than before surgery, and exercise tolerance is improved. Shortening of the upper jaw, incisor malalignment, or nostril collapse can develop if the procedure is performed in immature horses. Ideally, the surgery should be delayed until maturity.

Nasal Polyps

Nasal polyps are pedunculated growths that arise from the mucosa of the nasal cavity, nasal septum, or tooth alveolus. Polyps are usually unilateral and single but can be bilateral and multiple. They form in response to chronic inflammation by hypertrophy of the mucous membrane or exuberant proliferation of fibrous connective tissue. There is no age, breed, or gender predilection.

Clinical signs are poor airflow through the affected nasal passage; inspiratory dyspnea; unilateral, malodorous, mucopurulent nasal discharge; and low-volume epistaxis. The

mass may extend rostrally until it protrudes beyond the nostrils. Polyps are detected via endoscopic and radiographic examination, and histopathologic evaluation of biopsy samples provide a definitive diagnosis. Surgical excision is performed via an incision in the false nostril, a trephine opening, or a bone flap.

Choanal Atresia

Choanal atresia is caused by persistence of the bucconasal membrane that separates the primitive buccal or oral cavity from the nasal pits during embryonic development. Bilateral and unilateral cases have been described in horses. Clinical signs are evident immediately after birth in foals with bilateral disease, because dyspnea is severe and air cannot be detected passing through the nostrils. An endoscope or stomach tube passed through the ventral meatus will be obstructed at the level of the medial canthus of the eye.

Bilateral complete choanal atresia is a life-threatening condition, and a tracheotomy must be performed immediately after birth. It may be possible to perforate a thin membrane by electrocoagulation or laser or by excision through bilateral flaps centered along the midline. Indwelling tube stents should be inserted through both choanae and left in place for 6 wk.

DISEASES OF THE PARANASAL SINUSES

The maxillary sinus is the largest paranasal sinus and is divided by a thin septum into caudal and rostral parts. The frontal sinus has a large communication with the dorsal conchal sinus at its rostral end, thereby forming the conchofrontal sinus. The conchae or turbinates are delicate scrolls of bone that are attached laterally in the nasal passage and contain the conchal sinuses. The caudal and rostral maxillary sinuses have separate openings into the middle nasal meatus, and the caudal maxillary sinus communicates with the frontal sinus through the large frontomaxillary opening. Diseases that originate in one sinus cavity may extend to and involve others.

Most diseases of the paranasal sinuses cause mucopurulent or bloody nasal discharge. Drainage is unilateral, in contrast to disease of the lungs, pharynx, and guttural pouches, because the source of discharge is rostral to the caudal border of the nasal septum. Unilateral facial swelling, epiphora, dull percussion of the sinuses, and inspiratory noise are common manifestations of disorders of the sinuses.

On endoscopy, purulent material, a mass, or blood can be seen in the nasal passage originating from the nasomaxillary opening. Lateral and dorsoventral radiographs of the skull may reveal fluid lines, sinus cysts, solid masses, or lytic/proliferative changes associated with dental disease and neoplasia. Oblique projections in a dorsal to ventral direction may be required to improve views of the tooth roots. CT is useful, particularly for ventral conchal sinus disease. Centesis of the maxillary or frontal sinuses is performed to obtain fluid for bacterial culture, sensitivity testing, and cytologic examination. With sedation and local anesthesia, the sinuses can be examined in the standing horse by insertion of an arthroscope (4 mm). A second portal could be used to insert an instrument into the sinus to obtain specimens, debride tissue, and lavage the sinus cavity.

Sinusitis

Primary sinusitis occurs subsequent to an upper respiratory tract infection that has involved the paranasal sinuses. It usually involves all sinus cavities but can be confined to the ventral conchal sinus. This cavity is difficult to detect radiographically and access surgically. Secondary sinusitis can result from tooth root infection, fracture, or sinus cyst. The first molar, fourth premolar, and third premolar (in decreasing frequency) are the most likely to develop tooth root abscesses. Clinical signs of secondary sinusitis closely resemble those of primary sinusitis, including unilateral mucopurulent nasal discharge and facial deformity. Tooth root abscesses typically produce a fetid nasal discharge. Treatment of primary sinusitis involves lavage of the sinus cavity and systemic antimicrobial therapy based on culture and sensitivity results. Secondary sinusitis requires removal of affected cheek teeth or cystic material via sinusotomy.

Ethmoid Hematoma

Progressive ethmoid hematoma is a locally destructive mass of nasal passages and paranasal sinuses of uncertain etiology. The mass resembles a tumor in appearance and development but is not neoplastic. Large hematomas usually arise from the ethmoid labyrinth, and smaller masses arise from the floor of the sinuses. Masses originating in the sinus extend into the nasal passage. An expanding hematoma can cause pressure necrosis of surrounding bone but rarely causes facial distortion; it is primarily seen in horses

>6 yr old. Low-grade, spontaneous, intermittent, unilateral epistaxis is the most common clinical sign. Horses with extensive masses may have reduced airflow through the affected nasal passage and fetid breath. In longstanding cases, the mass may protrude from the nares. In most instances, the lesion can be seen extending into the nasal passages on endoscopic examination, and the extent of the mass can be determined radiographically. Conservative management includes intralesional injection of the mass with 4% formaldehyde. Formalin is injected into the mass using a guarded endoscopic needle. The mass typically regresses rapidly, but recurrence is common. Neurologic signs have been reported after intralesional formalin injection, associated with communication of the hematoma into the calvarium. Surgical excision is achieved via frontonasal bone flap.

Sinus Cysts

Sinus cysts are single or loculated fluid-filled cavities with an epithelial lining. They develop in the maxillary sinuses and ventral conchae and can extend into the frontal sinus. A congenital form has been described. Sinus cysts are typically found in horses <1 yr old but can also be seen in those >9 yr old. The primary clinical signs are facial deformity, nasal discharge, and partial airway obstruction. Radiographs are more likely to identify a sinus cyst than endoscopic examination. Multiloculated densities and fluid lines in the sinuses are observed radiographically; occasionally, dental distortion, flattening of tooth roots, soft-tissue mineralization, and deviation of the nasal septum are seen. Treatment involves radical surgical removal of the cyst and associated conchal lining. Prognosis for complete recovery is good, and the recurrence is low. Some horses may have a permanent, mild mucoid discharge after surgery.

GUTTURAL POUCH DISEASE

Empyema

Guttural pouch empyema is defined as the accumulation of purulent, septic exudate in the guttural pouch. The infection usually develops subsequent to a bacterial (primarily *Streptococcus* spp) infection of the upper respiratory tract. Clinical signs include intermittent purulent nasal discharge, painful swelling in the parotid area, and in severe cases, stiff head carriage and stertorous breathing. Fever,

Empyema of guttural pouch, horse, radiograph. Courtesy of Dr. Ronald Green.

depression, and anorexia may or may not be seen. Diagnosis is determined by endoscopic examination of the guttural pouch. Radiographs of the pharynx demonstrate a fluid line in the guttural pouch and may allow identification of an associated retropharyngeal mass.

Systemic antimicrobial therapy alone rarely resolves the infection; guttural pouch lavage is necessary. Penicillin gel (prepared using sodium penicillin) can be administered directly into the guttural pouch and may enhance bacterial clearance. Retropharyngeal abscesses can be resolved by rupturing the abscess into the guttural pouch using an endoscopic blade. If endoscopic rupture into the guttural pouch is unsuccessful, surgical drainage is necessary for retropharyngeal abscessation. Guttural pouch empyema may compress the dorsal pharynx and produce upper airway obstruction. Tracheotomy may be necessary to provide a temporary alternative airway in these cases. If guttural pouch empyema is not treated, chondroid material may form in the guttural pouch and serve as a source of chronic infectious exudate. A small number of chondroids can be removed endoscopically, but accumulations of exudate, chondroid material, or unresolved retropharyngeal abscesses require surgical drainage.

Guttural Pouch Mycosis

Mycotic plaques in the guttural pouch are typically located on the caudodorsal aspect of the medial guttural pouch, over the internal carotid artery. In some instances, fungal plaques may be multiple or diffuse. The most common fungal organism associated with guttural pouch mycosis is *Aspergillus* spp (see p 633). Clinical signs arise from damage to the cranial nerves and

the arteries within the mucosal lining of the guttural pouch. The most common sign is epistaxis, due to fungal erosion of the wall of either the internal carotid artery (most cases) or branches of the external carotid artery. Hemorrhage is spontaneous and severe, and repeated bouts may precede a fatal hemorrhagic episode. Dysphagia, Horner syndrome, and dorsal displacement of the soft palate may develop in response to fungal damage to cranial nerves and the sympathetic nerve that superficially traverse the guttural pouch. Dysphagia is a poor prognostic indicator and is highly correlated with nonsurvival. Diagnosis is determined by endoscopic examination of the guttural pouch. Treatment consists of topical and systemic antifungal therapy, based on sensitivity testing. Topical antifungal therapy is administered directly on the lesion via infusion through the biopsy channel of an endoscope. A fatal hemorrhagic event can be prevented by occluding the affected arteries along their course through the guttural pouch by means of a balloon-tipped catheter or a coil embolus. It is necessary to occlude the arteries proximal and distal to the lesion to prevent retrograde bleeding from the circle of Willis.

Guttural Pouch Tympany

Guttural pouch tympany is seen in horses ranging from birth to 1 yr of age and is more common in fillies than in colts. A genetic basis of disease has been identified in Arabian and German warmblood breeds. In some cases, the condition is acquired due to inflammation of the upper respiratory tract. The affected guttural pouch is distended with air and forms a characteristic nonpainful swelling in the parotid region. Breathing may become stertorous in severely affected animals. Tympany may result from inflammation or malformation of the pharyngeal orifice of the eustachian tube, which then acts as a one-way valve by allowing air to enter the pouch but preventing its return into the pharynx. Diagnosis is based on clinical

signs and radiographic examination of the skull. Severely affected animals may develop a secondary empyema. Tympany is usually unilateral, but bilateral cases have been reported. Medical management with NSAIDs and antimicrobial therapy resolves most cases due to upper respiratory tract inflammation. Surgical intervention is warranted in horses with malformation of the guttural pouch opening and involves fenestration of the membrane that separates the affected guttural pouch from the normal one. This provides a route for air in the abnormal guttural pouch to pass to the normal side and be expelled into the pharynx. The postoperative prognosis is good.

Rupture of the Longus Capitis Muscle

Traumatic rupture of the longus capitis is the second most common cause (after mycosis) of severe hemorrhage from the guttural pouch. The longus capitis muscle is one of the ventral straight muscles of the head. It inserts on the basisphenoid bone at the base of the skull. The point of rupture occurs at the insertion of the muscle dorsal to the guttural pouch. Rupture results from traumatic poll injury (rearing over backward) and produces profuse hemorrhage. Hemorrhage into the retropharyngeal space can cause asphyxia and death. On endoscopic examination, swelling and hemorrhage can be seen in the most rostral and medial aspects of the guttural pouch by retroflexion of the endoscope. On lateral radiographic examination, an avulsion fracture of the basisphenoid bone may be seen overlying the guttural pouch region. Significant neurologic deficits are often seen with this fracture. Treatment involves stall rest for 4–6 wk; broad-spectrum antibiotics are given for 5–7 days for any infection at the site of muscle rupture. Prognosis for full recovery is good, but persistent neurologic signs or recurrent hemorrhage worsens the prognosis.

RESPIRATORY DISEASES OF PIGS

Respiratory diseases of pigs can be classified into two broad categories based on the extent and duration of overt disease: those that affect large numbers of pigs and

may be serious but of limited duration, and those that persist in a large number of pigs for indefinite periods. Diseases in the first category can be costly, but the losses are

limited rather than ongoing. They include swine influenza (see p 1470), classical swine fever (see p 713), the pneumonic forms of pseudorabies (see p 1300), porcine circovirus-associated disease (see p 723), and porcine reproductive and respiratory syndrome (see p 729). The causal viruses may persist in a herd, but outbreaks of overt disease tend to be self-limiting.

The most important syndromes in the second category are mycoplasmal pneumonia and pleuropneumonia (see p 1467). Atrophic rhinitis, once considered to be a significant cause of respiratory disease in swine, has declined substantially as a result of eradication programs. Salmonellosis and *Haemophilus parasuis* infections may be significant problems in some herds. Moderate levels of atrophic rhinitis caused by *Bordetella bronchiseptica* alone may not be too significant but, when coupled with toxigenic strains of *Pasteurella*, are an important cause of economic loss due to decreased rate of growth and reduced feed conversion in young pigs. Enzootic pneumonia, when caused by mycoplasma alone, is of little consequence; however, when it is combined with secondary infection, eg, *Pasteurella multocida*, the resulting condition may be severe. *Actinobacillus pleuropneumoniae* may be associated with considerable losses in some herds. Migrating worm larvae or the infections listed in the first category often lead to severe problems when they occur with the infections in the second category.

The severity and economic importance of diseases in the second category also are related to population density and to the type and size of herd. They may be of little importance in weanling pig operations but become of major importance in high-density feeder-pig units. Although mortality usually is low, economic damage results from an adverse and uneven effect on growth rate, decreased feed efficiency, and additional costs of drugs, particularly medicated feed. However, when stress can be avoided by proper management, such diseases may result in only minimal losses.

Finally, it must be stressed that respiratory disease problems in pigs are frequently the result of multiple agents (co-infection) and rarely due to the effects of a single pathogen.

It is possible to set up herds free of diseases in the second category by techniques such as SPF repopulation or segregated early weaning, or by buying pigs from a pneumonia-free herd. The latter method is the least expensive, but because

the etiology of diseases in the second category is complex, all the pigs should be purchased from one source. This is also true when purchasing weaned pigs for feeder-pig units.

It is difficult to keep herds free of respiratory diseases. Aerosols have been suspected as sources of pathogen entry onto naive farms. Organisms such as *Mycoplasma hyopneumoniae* have been postulated to be transmitted over distances of as far as 2 miles, depending on climate, terrain, and density of pigs in the locality; however, this assumption is based on speculation and use of mathematical models rather than on experimental data.

Closed herds, ie, buying in no live animals (using artificial insemination or embryo transfer to bring in new genetic material), help establish immunity to present organisms and avoid introduction of new infections, strains, or serotypes. Multiple site production or an "all-in/all-out" policy, in which the entire barn or air space is emptied before refilling, can very effectively minimize the potential effect of chronic pneumonia.

Respiratory disease is endemic in many herds. The main control factors are stress management, stocking density, ventilation, temperature control, and freedom from mixing and moving. Multiple site production or "all-in/all-out" and closed-herd management practices greatly decrease the need for preventive and therapeutic medication.

ATROPHIC RHINITIS

Atrophic rhinitis is characterized by sneezing, followed by atrophy of the turbinate bones, which may be accompanied by distortion of the nasal septum and shortening or twisting of the upper jaw. Its significance has declined substantially, and it is no longer considered a major health risk to swine herds.

Etiology: The etiology is complex and involves at least two organisms. Various infections (eg, inclusion body rhinitis and pseudorabies) and noninfectious agents (eg, dust or high ammonia levels) cause sneezing and tear-staining, usually without leading to atrophic rhinitis. *Bordetella bronchiseptica* has long been implicated as a major cause. This bacterium is not host-specific, although strains that cause atrophic rhinitis are generally isolated only from pigs. Dogs, cats, rodents, and other species may harbor *B. bronchiseptica* for long periods, but their role in the spread of atrophic rhinitis in pigs is uncertain.

Atrophic rhinitis in a pig. The nasal turbinate bones have been completely destroyed after natural infection with type D toxigenic *Pasteurella multocida*. Courtesy of the Department of Pathology, University of Guelph.

Toxigenic strains of *Pasteurella multocida* (type D), often acting with *B bronchiseptica*, cause permanent turbinate atrophy and nasal distortion. Both organisms can cause clinical atrophic rhinitis.

The disease has been divided into two forms: **nonprogressive** atrophic rhinitis, due to *B bronchiseptica*, is mild and transient and probably does not greatly affect the animal's growth and performance; **progressive** atrophic rhinitis, due to toxigenic *P multocida*, is severe, permanent, and usually accompanied by poor growth.

Outbreaks of disease usually follow either the introduction of infected pigs or mixing of pigs from different sources. Piglets may be affected at any age, especially with *P multocida*, which also may infect mature animals. Crowding, inadequate ventilation, mixing and moving, and other concurrent diseases are important contributory factors in intensification of the disease.

Clinical Findings: Acute signs, which usually appear at 3–8 wk of age, include sneezing, coughing, and inflammation of the lacrimal duct. In more severe cases, nasal hemorrhage may occur. The lacrimal ducts may become occluded, and tear stains then

appear below the medial canthi of the eyes. Some severely affected pigs may develop lateral deviation or shortening of the upper jaw, whereas others may suffer some degree of turbinate atrophy with no apparent outward distortion. The degree of distortion can be judged from the relationship of the upper and lower incisors if breed variations are considered. In addition to the above clinical signs, outbreaks frequently impair growth rate and feed conversion.

The severity of atrophic rhinitis in a herd depends largely on the presence of toxigenic strains of *P multocida*, the level of management, and the immune status of the herd. The latter is related to both vaccination status and the parity distribution of the sow herd, because younger sows tend to shed more organisms and produce less lactogenic immunity for their nursing piglets than do older multiparous sows.

Lesions: The degree of atrophy and distortion is best assessed by examining a transverse section at the level of the second premolar tooth (the first cheek tooth, up to 7–9 mo of age); some recommend additional parallel sections. In the active stages of inflammation, the mucosa has a blanched appearance, and purulent material may be present on the surface. In later stages, the nasal cavities may be clear, but there may be variable degrees of softening, atrophy, or grooving of the turbinates; deviation of the nasal septum; and asymmetric distortion of the surrounding bone structure.

Diagnosis: The signs and lesions are commonly the basis for diagnosis; however, the presence of toxigenic strains of *P multocida* should be confirmed. Routine monitoring is done in some breeding herds by measuring the degree of turbinate atrophy and giving the herd an atrophy score. Atrophic rhinitis must be differentiated from necrotic rhinitis (see p 1468).

Control: It is rarely possible to keep herds entirely free from mild outbreaks of sneezing, and a low level of aberrant turbinates and nasal bones at necropsy is common, even in herds that show no clinical signs of rhinitis. When atrophic rhinitis rises to an unacceptable level in a herd, control measures are usually strategic: chemoprophylaxis, vaccination, temporary closure of the herd to introduction of new pigs, and improved management (eg, better ventilation and hygiene, less dusty feed). Chemoprophylaxis usually includes administration of antibacterial drugs to all sows, particularly before farrowing, as well as programs of

repeated medications for newborn piglets and sometimes for newly weaned pigs. Medication of weaner and grower rations, and sometimes sow rations, is often helpful. Drugs commonly used are ceftiofur, sulfonamides, tylosin, and tetracyclines.

Bacterins against toxigenic *P multocida* and *B bronchiseptica* have been developed. Both toxoid vaccines and bacterin-toxoid mixtures are available against *P multocida*; although both give satisfactory results in most herds, infection can be best prevented with bacterin-toxoid mixtures. Typically, sows are vaccinated 4 and 2 wk before farrowing, and the young pigs at 1 and 4 wk of age. However, vaccination schedules recommended by the manufacturer should be followed. A high level of colostral immunity is acquired by piglets nursing vaccinated sows. An intranasal vaccine using modified-live strains of *B bronchiseptica* is also available for young pigs.

MYCOPLASMA PNEUMONIA

(Enzootic pneumonia)

Mycoplasmal pneumonia is a chronic, clinically mild, infectious pneumonia of pigs, characterized by its ability to become endemic in a herd and to produce a persistent dry cough, retarded growth rate, sporadic "flare-ups" of overt respiratory distress, and a high incidence of lung lesions in slaughter pigs. It occurs worldwide.

Clinical outbreaks of mycoplasmal pneumonia may impair growth rate and feed conversion. This effect is enhanced when large numbers of pigs are closely confined in poorly ventilated buildings under poor husbandry conditions. The effects of the disease are uneven and unpredictable and place limits on the efficiency and flexibility of large production units. However, in swine units with good disease control measures, mycoplasmal pneumonia may remain largely subclinical and is of little economic importance.

Etiology and Epidemiology: The terms "viral pneumonia" and "enzootic pneumonia" are frequently used to describe a characteristic disease syndrome now known to be caused primarily by *Mycoplasma hyopneumoniae*. The pleomorphic organism is fastidious, smaller than most bacteria, and difficult to see clearly under ordinary light microscopes. It can be cultured in specially prepared media, but isolation from field

cases is difficult. It is rapidly inactivated in the environment and by disinfectants, but it may survive longer in cold weather. It appears to be host-specific.

Mycoplasmal pneumonia is also frequently complicated by other mycoplasmas, bacteria, and viruses, which affect the severity of the disease. Certain strains of *M hyorhinis*, and perhaps some viruses, may themselves act as primary agents to produce a syndrome resembling the pneumonia caused by *M hyopneumoniae*.

In most countries that use modern pig-farming methods, the lungs of 30%–80% of the pigs slaughtered show pneumonic lesions of the type associated with mycoplasmal infection. Pigs of all ages are susceptible, but within a herd, pigs become infected in the first few weeks of life either by their dam or by other young pigs after mixing. Transmission to lactating piglets can occur from sows of all parities but is most prevalent in first-parity (gilt) litters. In addition, with the adaptation of segregated (multisite) production, the onset of the disease has been delayed and may be most evident in the finishing stage at ~18–20 wk of age. The incidence of lung lesions is highest in pigs 3–5 mo old. Immunity develops slowly, followed by regression of the lung lesions. Older growing and mature pigs may recover completely.

Clinical Findings: In herds in which the disease is endemic, morbidity is high, but clinical signs may be minimal and mortality is low. Coughing is the most common sign and is most obvious when pigs are roused. Individual pigs or groups sporadically develop severe pneumonia. A common predisposing factor is a change of weather, but other stresses (eg, transient viral infections, parasitic migration, and mixing pigs) may also cause outbreaks. The disease is usually more severe when it first enters a naive herd.

Lesions: Affected lungs are gray or purple, most commonly in the apical and cardiac lobes. Old lesions become clearly demarcated. The associated lymph nodes may be enlarged. Histologically, inflammatory cells are present in the bronchioles; there is perivascular and peribronchiolar cuffing and extensive lymphoid hyperplasia.

Diagnosis: Clinical, pathologic, and epidemiologic findings are usually adequate for diagnosis. *M hyopneumoniae* can be demonstrated in impression smears of

the cut surface of affected lung, identified by fluorescent antibody technique, and sometimes isolated and identified in culture. Serologic tests, principally the complement fixation test, and ELISA are occasionally used on a herd basis, but results may be difficult to interpret. A PCR test to detect *M hyopneumoniae* in nasal and bronchial swabs has been developed and appears to be very sensitive and specific.

Control: When the disease first enters a herd, mass treatment with antibiotics (eg, tylosin, lincomycin, tiamulin, or a tetracycline) helps to control the severity of signs. When disease increases in endemic herds, treatment of individual pigs with antibiotics usually results in remission, presumably by controlling secondary bacteria.

Inactivated mycoplasmal cultures have been developed as bacterins and consist of whole-cell preparations as well as new subunit bacterins. These induce excellent protection against development of gross lesions and significantly reduce clinical signs (coughing) in growing pigs. Data indicate that prefarrowing vaccination of sows with *M hyopneumoniae* vaccines significantly reduces colonization of suckling piglets.

The economic effects of the disease can be reduced, and sometimes eliminated, by improvements in housing and husbandry, particularly ventilation and overcrowding, along with medication and vaccination. "All-in/all-out" management of pigs from birth to market is extremely effective at reducing negative effects of disease; following this practice improves growth performance and reduces lung lesions.

In large intensive units, starting with foundation stock free of mycoplasmal pneumonia and adopting strict precautions against direct and indirect contact with pigs from other herds is advisable. Unfortunately, many herds set up in this way do not remain free of mycoplasmas for very long, particularly in areas with a high density of pigs. Field observations suggest that infection can be windborne for at least a mile between large herds in cold, wet weather.

In the USA and parts of Europe, most herds free of mycoplasmal pneumonia were established by the pig repopulation technique. More recently, some have been established by segregated early weaning. The biggest problems with these herd programs are the breakdown rate and the difficulty of monitoring

herds that claim to be free of mycoplasmal pneumonia. Hypotheses for these outbreaks suggest that the organism may never have been successfully eliminated in certain herds, but rather coexisted within the population at an undetectable level for extended periods. Use of nasal swab PCR technology has demonstrated presence of the organism in pigs free of clinical signs, lesions, and antibodies. Analysis of tracheal sections from these pigs by electron microscopy has indicated presence of the organism on the cilia.

NECROTIC RHINITIS

(Bullnose)

Necrotic rhinitis is an uncommon, sporadic disease of young pigs characterized by suppurative and necrosis of the snout, arising from wounds of the oral or nasal mucosa. Confusion exists in the literature because of the use of the misnomer "bullnose" to also describe atrophic rhinitis (see p 1465).

Etiology: *Fusobacterium necrophorum* is commonly isolated from the lesion and undoubtedly contributes to the disease, but other types of organisms are frequently present. They gain entry through damage to the roof of the mouth, often as a result of clipping the needle teeth too short or using blunt clippers.

Clinical Findings and Lesions: Signs include swelling and deformity of the face, occasionally hemorrhage, snuffling, sneezing, foul-smelling nasal discharge, sometimes involvement of the eyes with lacrimation and purulent discharge, loss of appetite, and emaciation. Generally, only one or two pigs in a herd are affected.

The facial swelling usually is hard, but incision reveals a mass of pinkish gray, foul-smelling necrotic tissue, or greenish gray tissue debris, depending on the age of the lesion. The nasal and facial bones become involved, and facial deformity may be marked.

Diagnosis: Necrotic rhinitis is readily differentiated from atrophic rhinitis by the bulging type of facial distortion seen in the former. The character of the exudate and its location within the tissue of the snout or face are also distinctive of necrotic rhinitis.

Prevention and Treatment: Prevention is directed toward avoiding injuries to the

mouth and snout, improving pig processing techniques, and improving sanitation. When the disease occurs repeatedly, needle teeth should be clipped carefully.

If the condition is advanced, treatment may not be advisable. Early surgical intervention and packing the cavity with sulfonamide or tincture of iodine may be useful. In young pigs, sulfamethazine given PO is of value.

PASTEURELLOSIS

Pasteurellosis is most commonly seen in pigs as a complication of mycoplasmal pneumonia (see p 1438), although swine influenza, Aujeszky disease, *Bordetella bronchiseptica*, or *Haemophilus paraahaemolyticus* may also cause changes in the lungs that lead to disease caused by *Pasteurella* spp. The causative organism usually is *P. multocida*. A normal inhabitant of the porcine upper respiratory tract, it produces an exudative bronchopneumonia, sometimes with pericarditis and pleuritis. Primary, sporadic, fibrinous pneumonia due to pasteurellae, with no epidemiologic connection with mycoplasmal or other pneumonia, may also be seen in pigs. In both primary and secondary forms, chronic thoracic lesions and polyarthritis tend to develop. Diagnosis is based on necropsy findings and recovery of pasteurellae from the lesions. Nontoxigenic strains of capsular type A are the predominant isolates from cases of pneumonia. Toxigenic strains of *P. multocida*, in the presence of *B. bronchiseptica*, are now associated with atrophic rhinitis (see p 1465).

Septicemic pasteurellosis and meningitis occasionally occur in piglets. *Mannheimia haemolytica* has been recovered from aborted fetuses, and septicemia may also occur in adult pigs. There are no distinctive lesions, and the pathogenesis is obscure. Porcine strains of *M. haemolytica* are often untypeable and do not belong to the common ovine and bovine serotypes. However, some outbreaks in the UK have been associated with close contact with sheep.

Control of the secondary, pneumonic form of the disease is generally based on prevention or control of mycoplasmal pneumonia. Early and vigorous therapy with antibiotics, or in combination with sulfonamides, is indicated to prevent chronic sequelae of all forms of the disease. An increasing resistance to some antibiotics has been noted among the pasteurellae.

PLEUROPNEUMONIA

Pleuropneumonia is a severe and contagious respiratory disease, primarily of young pigs (≤ 6 mo old), although in an initial outbreak, adults also may be affected. It has a sudden onset, short course, and high morbidity and mortality. It occurs worldwide and appears to be increasing in incidence, although some reports suggest that severity is declining in countries where it has been long established.

Etiology: The causal organism is *Actinobacillus pleuropneumoniae*. To date, 15 serotypes have been identified; they vary widely in virulence and significance across countries. Historically, serotypes 1, 5, and 7 have been prevalent in the USA. Transmission is mainly by nose-to-nose contact, and many recovered pigs are carriers. Clinical signs develop within 4–12 hr in experimental infections. Aerosol transmission is limited.

Clinical Findings: Onset is sudden, and in herds that have not been infected previously, spread is rapid. Some pigs may be found dead without having shown clinical signs. Respiratory distress is severe; there are “thumps,” and sometimes open-mouth breathing with a blood-stained, frothy nasal and oral discharge. Fever up to 107°F (41.5°C), anorexia, and reluctance to move are typical signs.

Although primarily a disease of growing pigs, *A. pleuropneumoniae* infection may be fatal in adults or cause sows to abort. The course of the disease varies from peracute to chronic. Morbidity may reach 50%, and in untreated cases, mortality is high. Survivors generally show reduced growth rates and persistent cough.

Once established in a herd, the disease may be evident only as a cause of reduced growth rate and pleurisy at the abattoir, although acute disease exacerbations may occur. However, severe lesions may not always be accompanied by equally severe clinical signs. Deaths in transit and carcass condemnation may result. Concurrent infection with mycoplasma, pasteurellae, porcine reproductive and respiratory syndrome, or swine influenza virus is common.

Lesions: The pneumonia is usually bilateral. The characteristic lesion is a severe fibrinonecrotic and hemorrhagic pneumonia with accompanying fibrinous pleuritis. Fibrinous pleuritis and pericarditis may be severe. In acute cases, the lungs are

dark and swollen and ooze bloody fluid from the cut surface; hemorrhagic, even necrotic, bullae of various sizes may be present. The trachea may contain blood-stained froth. In chronic cases, the lesions are more organized and localized. Extrathoracic lesions are uncommon.

Diagnosis: An explosive disease onset is suggestive and, when combined with clinical signs and gross lesions, often justifies a tentative diagnosis. Concurrent infections, eg, with pasteurellae, may complicate diagnosis. In herds that have been exposed and have developed at least a degree of immunity, the pattern may be less distinctive. Many serologic tests, including complement fixation and ELISA, have been used to confirm a herd diagnosis or detect carriers, but results are not always straightforward. A definitive diagnosis depends on isolation and identification of *A pleuropneumoniae*, a gram-negative coccobacillus that requires V factor (NAD) supplementation for growth. A *Staphylococcus aureus* nurse colony can provide the necessary factor. PCR testing is also available and provides better sensitivity than direct culture.

Treatment and Control: Rapidity of onset and persistence in infected herds make treatment difficult. Ceftiofur, tilmicosin, tetracyclines, synthetic penicillins, tylosin, and sulfonamides have been used. The first treatment should be parenteral, followed by medication given in water or feed, which also may protect contact pigs.

Because survivors frequently remain carriers, control is difficult, although good results are being claimed for some vaccines. Segregated early weaning, "all-in/all-out" management, reduced stocking rates when possible, and improved ventilation are recommended. In herds free of the disease, replacements should be purchased from herds free of *A pleuropneumoniae*; if the disease proves difficult to control, herd depopulation and repopulation should be considered. Serologic testing effectively detects previously infected herds but may not identify carrier animals.

SWINE INFLUENZA

(Hog flu, Pig flu)

Swine influenza is an acute, highly contagious, respiratory disease that results from infection with type A

influenza virus. Field isolates of variable virulence exist, and clinical manifestation may be determined by secondary organisms. Pigs are the principal hosts of classic swine influenza virus. (Human infections have been reported, but porcine strains of influenza A do not appear to easily spread in the human population. However, deaths have occurred in immunocompromised people.) In 2009, a pandemic strain of H1N1 influenza A virus spread globally; it infected people, swine, and poultry, as well as a small number of dogs, cats, and other animals. The disease in swine occurs commonly in the midwestern USA (and occasionally in other states), Mexico, Canada, South America, Europe (including the UK, Sweden, and Italy), Kenya, China, Japan, Taiwan, and other parts of eastern Asia.

Etiology: Swine influenza virus (SIV) is an orthomyxovirus of the influenza A group with hemagglutinating antigen H1 and neuraminidase antigen N1 (ie, H1N1). Recently, new subtypes of SIV have been reported (H3N2, H1N2, and H2N3). Influenza B and C viruses have been isolated from pigs but have not caused the classic disease. The classic type A infection with isolates of mild virulence may favor replication of pseudorabies virus (see p 1300), *Haemophilus parasuis* (Glässer's disease, see p 720), *Actinobacillus pleuropneumoniae* (see above), and *Mycoplasma hyopneumoniae* (see p 1467), any of which may complicate outbreaks. The mixing of carrier and nonimmune pigs is an important predisposing factor. The virus is unlikely to survive outside living cells for >2 wk except in cold conditions. It is readily inactivated by disinfectants.

Transmission and Epidemiology:

In North America, outbreaks are most common in fall or winter, often at the onset of particularly cold weather. In warmer areas of the world, infection may occur at any time. Usually, an outbreak is preceded by one or two individual cases and then spreads rapidly within a herd, mainly by aerosolization and pig-to-pig contact. The virus survives in carrier pigs for up to 3 mo and can be recovered from clinically healthy animals between outbreaks. In antibody-positive herds, outbreaks of infection recur as immunity wanes. Up to 40% of herds may contain antibody-positive pigs. Carrier pigs are usually responsible for the introduction of SIV into previously uninfected herds and countries.

Pathogenesis: The spectrum of infection ranges from subclinical to acute. In the classic acute form, the virus multiplies in bronchial epithelium within 16 hr of infection and causes focal necrosis of the bronchial epithelium, focal atelectasis, and gross hyperemia of the lungs. Bronchial exudates and widespread atelectasis, grossly appearing as plum-colored lesions affecting individual lobules of apical and intermediate lobes, are seen after 24 hr. The lesions continue to develop until 72 hr after infection, after which the virus becomes more difficult to demonstrate. Losses in reproduction associated with primary outbreaks appear to be secondary, because virus has been recovered only rarely from the fetus.

Clinical Findings: A classic acute outbreak is characterized by sudden onset and rapid spread through the entire herd, often within 1–3 days. The main signs are depression, fever (to 108°F [42°C]), anorexia, coughing, dyspnea, weakness, prostration, and a mucous discharge from the eyes and nose. Mortality is generally 1%–4%. The overt course of the disease is usually 3–7 days in uncomplicated infections, with clinical recovery of the herd almost as sudden as the onset. However, virus may continue to cycle among pigs when clinical signs are suppressed by immune responses. Some pigs may become chronically affected. In herds that are in good condition, the principal economic loss is from stunting and delay in reaching market weight. Some increase in piglet mortality has been reported, and effects on herd fertility, including abortions in late pregnancy, may follow outbreaks in nonimmune herds.

Lesions: In uncomplicated infections, lesions usually are confined to the thoracic cavity. The pneumonic areas are clearly demarcated, collapsed, and purplish red. They may be distributed throughout the

lungs but tend to be more extensive and confluent ventrally. Nonpneumonic areas are pale and emphysematous. The airways contain a copious mucopurulent exudate, and the bronchial and mediastinal lymph nodes are edematous but rarely congested. There may be severe pulmonary edema, especially of interlobular septae, or a serous or serofibrinous pleuritis. Histologically, the lesions, when fully developed, are primarily those of an exudative bronchiolitis with some interstitial pneumonia.

Diagnosis: A presumptive diagnosis can be made on clinical and pathologic findings, but confirmation depends on detection of viral RNA via PCR, molecular sequencing, or demonstration of virus-specific antibody. Virus can be isolated from nasal secretions in the febrile phase or from affected lung tissue in the early acute stage. A retrospective diagnosis can be made by demonstrating a rise in virus-specific antibodies in acute and convalescent serum samples using the hemagglutination inhibition test. Both H3 and H1 subtype antigens should be included. This test is also used for herd surveys. To diagnose uncomplicated influenza infection, conditions such as pasteurellosis, pseudorabies, porcine reproductive and respiratory syndrome, and chlamydial and *Haemophilus* infections must be excluded.

Treatment and Control: There is no effective treatment, although antimicrobials may reduce secondary bacterial infections. Expectorants may help relieve signs in severely affected herds. Vaccination and strict import controls are the only specific preventive measures. Good management practices and freedom from stress, particularly due to crowding and dust, help reduce losses. Commercially available killed vaccines that contain both H1N2 and H3N2 subtypes appear to induce a strong protective immune response.

RESPIRATORY DISEASES OF SHEEP AND GOATS

Upper Respiratory Tract: Diseases of the upper respiratory tract of sheep and goats include sinusitis caused by the larvae of *Oestrus ovis*, nasal foreign bodies, and nasal tumors. Clinical signs associated with

sinusitis may include some or all of the following: unilateral or bilateral, serous to mucopurulent nasal discharge; decreased or lack of airflow through one or both nostrils; coughing; sneezing; and mild to severe

respiratory distress. The types of nasal neoplasms reported include adenopapillomas (nasal polyps), adenomas, adenocarcinomas, lymphosarcomas (goats), and squamous cell carcinomas (sheep).

Enzootic nasal tumor is caused by an exogenous retrovirus referred to as enzootic nasal tumor virus (ENTV). It can be transmitted experimentally by tumor homogenates, which would explain the widespread occurrence of this condition within some flocks. This type of tumor generally affects mature animals (2–4 yr old), although it has been reported in animals as young as 4 mo old. The lesion may be unilateral or bilateral, resulting in either unilateral or bilateral serous, mucoid, or mucopurulent nasal discharge. Advanced unilateral tumors may cause deviation of the nasal septum, resulting in bilateral nasal discharge. Affected animals show progressive signs of dyspnea (inspiratory), including open-mouth breathing, decreased airflow as measured at the nares, dullness on percussion over the turbinates, sneezing, and head-shaking. Stridor may also be caused by compression of the larynx by enlarged retropharyngeal lymph nodes associated with abscessation of the head. Laryngeal chondritis also results in inspiratory dyspnea of varying severity. With advancing tumor growth, exophthalmos and facial deformity may occur. Metastatic spread is uncommon. Outcome depends on the tumor type, condition of the animal, and extent of the lesion, but in most commercial situations the animal is culled for animal welfare and commercial reasons. Surgical removal of a noninvasive tumor is rarely undertaken.

The most common problems associated with the pharynx are trauma and abscessation. Pharyngeal trauma usually results from overly aggressive use of equipment used to administer boluses. Injuries may result in the formation of discrete abscesses or extensive and diffuse cellulitis, both of which can interfere with swallowing and possibly lead to respiratory difficulty or distress. Bacteria commonly isolated after an incident of pharyngeal trauma include *Trueperella*, *Pasteurella multocida*, *Mannheimia haemolytica*, and *Fusobacterium*.

Laryngeal chondritis is an obstructive upper respiratory tract disease characterized by severe dyspnea most commonly encountered in meat-breed rams 18–24 mo old. Acute onset of severe respiratory distress with marked inspiratory effort and stertor is caused by edema of the arytenoid

cartilages of the larynx, resulting in narrowing of the lumen. Affected sheep stand with the neck extended, head held lowered with flared nostrils, and mouth open; they are reluctant to move because of dyspnea. Delayed identification and/or inadequate duration of antibiotic therapy may result in abscess formation within the arytenoid cartilages.

Lower Respiratory Tract: The most common problem associated with the lower respiratory tract is pneumonia. Pneumonias can be caused by viruses, bacteria, or parasites. They can be acute, chronic, or progressive.

Viruses associated with acute pneumonia include parainfluenza type 3 (PI-3), adenovirus, and respiratory syncytial virus. These viral pneumonias most often affect lambs and kids.

PI-3 is an enveloped RNA virus (family Paramyxoviridae) that induces a mild interstitial pneumonia. Clinical signs may include coughing, serous nasal and/or ocular discharge, fever (104°–106°F [40°–41°C]), and an increased respiratory rate. The single PI-3 serotype for sheep that has been identified is distinct from the bovine PI-3 serotype. Infection with this virus can be confirmed by its isolation from nasal swabs from affected animals, or by comparison of acute and convalescent serum antibody levels. Treatment is usually not warranted in mildly affected animals. In severely affected animals in which secondary pathogens are suspected, antimicrobial therapy is recommended using drugs with efficacy against the most likely organisms, such as *P. multocida*, *M. haemolytica*, and *Mycoplasma* sp. There are no PI-3 vaccines specifically designed for use in small ruminants.

Chronic, progressive viral pneumonia is most common in adults and includes progressive interstitial retroviral pneumonia (in sheep, ovine progressive pneumonia or maedi [see p 1475]; in goats, pneumonia induced by arthritis encephalitis virus [see p 747]) and ovine pulmonary adenocarcinoma (see p 1477), also known as jaagsiekte or the contagious lung tumor of sheep and, infrequently, of goats.

Chronic, progressive, proliferative changes in the lungs are usually associated with the lentiviruses (family Retroviridae), or so-called slow-virus infections. In both progressive pneumonia and pulmonary adenocarcinoma, the entire lung can change in a gradual process of abnormal cellular

proliferation. In affected sheep, the loss of functional lung tissue results in progressive dyspnea, anorexia, and weight loss.

M haemolytica, *P multocida*, *Mycoplasma* spp, *Chlamydia pneumoniae*, and *Salmonella* spp are associated with either primary or secondary bronchopneumonia in sheep and goats. Both *P multocida* and *M haemolytica* can be cultured from the upper respiratory tract of normal sheep and goats. Not all factors predisposing to acute respiratory diseases are known, but acute viral infections in a susceptible population can alter the protective mechanisms in the respiratory tract so that certain bacteria may invade lung tissue, multiply, and cause serious disease. An initial infection with PI-3 virus may predispose an animal to infection with pathogenic *M haemolytica*. Also, *Mycoplasma ovipneumoniae* alone can cause a mild bronchopneumonia; however, it is often isolated along with *M haemolytica* from sheep and goats with severe pneumonia, suggesting that the *Mycoplasma* may predispose the lung to invasion by this organism. Additionally, introduction of new animals, high-density stocking, poor ventilation, and a sudden change to a high plane of nutrition can act as stress factors that predispose to development of pneumonia.

Caseous lymphadenitis (see p 63) caused by *Corynebacterium pseudotuberculosis* may result in abscessation of the lungs and mediastinal lymph nodes. This can result in a progressive debilitation in sheep and goats with or without obvious clinical signs of respiratory disease.

Parasitic or verminous pneumonias of sheep and goats are most commonly caused by infection with *Dictyocaulus filaria*, *Muellerius capillaris*, or *Protostrongylus rufescens*. (See also p 1421.) In contrast to the acute viral and bacterial pneumonias, which result in a bronchopneumonia affecting the anterior ventral portion of the lungs, verminous pneumonia affects the margins of the diaphragmatic lung lobes. *Dictyocaulus* has a direct life cycle, whereas *Protostrongylus* and *Muellerius* have indirect life cycles and rely on a variety of snails and slugs to serve as intermediate hosts. Adult forms of *Dictyocaulus* and *Protostrongylus* live in bronchi but rarely cause clinical signs. Adult *Muellerius* live in alveoli and lung parenchymal tissue and are considered the least pathogenic of the three lungworms. *Muellerius* appears to cause more problems for goats than for sheep.

Diagnosis of lungworm infection requires Baermann examination of fecal material

(See also p 1619). Treatment for lungworm infection is rarely indicated; however, it is likely that sheep with such infections will also carry other nematodes that will cause parasitic gastroenteritis and limit production.

SHEEP NOSE BOT

The sheep nose bot fly, *Oestrus ovis*, is a cosmopolitan parasite that, in its larval stages, inhabits the nasal passages and sinuses of sheep and goats. Its geographic distribution is worldwide.

The adult fly is grayish brown and ~12 mm long. The female deposits larvae in and about the nostrils of sheep without alighting. These small, clear-white larvae (initially <2 mm long) migrate into the nasal cavity; many spend at least some time in the paranasal sinuses. The larval period, which is usually shortest in young animals, lasts 1–10 mo. When mature, the larvae leave the nasal passages, drop to the ground, burrow down a few inches, and pupate. The pupal period lasts 3–9 wk, depending on the environmental conditions, after which the fly emerges from the pupal case and pushes its way to the surface. Mating soon occurs, and the female begins to deposit larvae.

Clinical Findings: Once the larvae begin to move about in the nasal passages, a profuse discharge occurs, at first clear and mucoid, but later mucopurulent and frequently tinged with fine streaks of blood emanating from minute hemorrhages produced by the hooks and spines of the larvae. Paroxysms of sneezing accompany migrations of the larger larvae. Larvae present in the sinuses are sometimes unable to escape; they die and may gradually become calcified or lead to a septic sinusitis. However, the principal effects are annoyance, with a resulting reduction in grazing time, and loss of condition. Usually only 4–15 larvae are found, although many more may be present.

To avoid the fly's attempts at larval deposition, a sheep may run from place to place, keeping its nose close to the ground, sneeze and stamp its feet, or shake its head. Commonly, especially during the warmer hours of the day when the flies are most active, small groups of sheep gather and face the center of a circle, heads down and close together.

Treatment: Ivermectin at 200 mcg/kg, PO or SC, is highly effective against all stages of the larvae.

CONTAGIOUS CAPRINE PLEUROPNEUMONIA

Contagious caprine pleuropneumonia is a highly fatal disease that occurs in goats in the Middle East, Africa, and Asia. It was seen for the first time on European soil in Thrace, Turkey, in 2002, but does not appear to have spread to neighboring countries, Greece and Bulgaria. Outbreaks have recently been reported in sheep and captive wildlife, including gazelles and small ruminants.

Etiology: *Mycoplasma capricolum capripneumoniae* (*Mycoplasma* biotype F38) is the causative agent. It appears to be transmitted by infective aerosol. Morbidity can be 100%, and mortality 60%–100%. The disease is introduced into a new region by healthy carriers. Gathering or housing animals together facilitates spread of the disease.

Pneumonia and pleuropneumonia can be caused by other mycoplasmas, including *M. mycoides capri*. Taxonomic change means this subspecies also includes *M. mycoides mycoides* large colony type. Morbidity and mortality rates are generally lower with *M. mycoides capri*, and joint and udder infections may also be seen.

Clinical Findings: Weakness, anorexia, cough, hyperpnea, and nasal discharge accompanied by fever (104.5°–106°F [40.5°–41.5°C]) are often found. Exercise intolerance progresses to respiratory distress, with open-mouth breathing and frothy salivation. A septicemic form of the disease without specific respiratory tract involvement has been described.

Lesions: Typically, there is an excess of straw-colored pleural exudate and acute fibrinous pneumonia. Consolidation is sometimes confined to one lung. The distention of interlobular septa by serofibrinous fluid, commonly seen in infections caused by *M. mycoides capri*, is rarely seen in contagious caprine pleuropneumonia. In antibiotic-treated or recovered animals, the predominant lesion is a sequestrum similar to that seen in contagious bovine pleuropneumonia.

Diagnosis: The clinical signs, epidemiology, and necropsy findings are used to establish a diagnosis. The causative organism should be isolated and identified, but isolation may be difficult, and special media is required for culture. PCR, which can be performed directly on the pleural

fluid or affected lung, has greatly facilitated the diagnosis of contagious caprine pleuropneumonia. Serologic tests are complement fixation, passive hemagglutination, and ELISA; the latex agglutination test can be done in the field directly on whole blood as well as on serum samples in the laboratory. Serologic cross-reactions may occur with other members of the *Mycoplasma mycoides* cluster.

Control: Quarantine of affected flocks is desirable. Vaccines are available in some countries, and good to excellent protection has been reported. Treatment with tylosin at 10 mg/kg/day, IM, for 3 days, has been effective, as has oxytetracycline (15 mg/kg).

PASTEURELLA AND MANNHEIMIA PNEUMONIAS

Bronchopneumonia caused by *Pasteurella multocida* or *Mannheimia haemolytica* has a cranioventral lung distribution and affects sheep and goats of all ages worldwide. It can be particularly devastating in young animals around weaning. It is a common cause of morbidity and mortality in lambs and kids, especially in those that have not received adequate colostrum or in which passive colostral immunity is waning. The disease appears to occur most often in animals that have undergone recent stress such as transportation, weaning, change of diet, or commingling with animals from unrelated farms. *Bibersteinia trehalosi* (formerly *Pasteurella trehalosi*) causes septicemia in lambs 4–9 mo old (systemic pasteurellosis). (See also PASTURELLOSIS OF SHEEP AND GOATS, p 765.)

Etiology: *P. multocida* and *M. haemolytica* are commensals of the upper respiratory tract that can cause pneumonia either alone or in conjunction with other organisms. Primary infections with respiratory pathogens such as parainfluenza type 3, adenovirus, respiratory syncytial virus, *Bordetella parapertussis*, or in particular *Mycoplasma ovipneumoniae* appear to predispose to secondary infection with *Pasteurella* and *Mannheimia*.

Pathogenesis: Stress appears to be an important factor that allows *Pasteurella*, *Mannheimia*, *Mycoplasma ovipneumoniae*, other bacteria, and viruses to multiply and impair the normal physical defense mechanisms, facilitating invasion of lung tissue and development of pneumonia. In

calves, alveolar macrophage function is impaired after viral pneumonia. This results in decreased clearance of inhaled bacterial pathogens, allowing them to become established. Pathogen-host interactions result in tissue damage, especially because of massive influx of neutrophils. As these neutrophils are lysed, enzymes are released that cause more lung tissue damage. This mechanism may be similar to that of *Pasteurella* and *Mannheimia* pneumonias in sheep and goats.

Clinical Findings: Acute respiratory disease caused by *M haemolytica* is uncommon in adult sheep, unless there is a predisposing problem such as ovine pulmonary adenocarcinoma or other viral infection. Clinical signs include acute onset depression, lethargy, and inappetence and are consistent with profound endotoxemia. Sudden death may occur without clinical signs having been observed. Affected sheep are typically separated from the remainder of the flock and are easily caught and restrained. On approach, they may show an increased respiratory rate with an abdominal component.

Affected sheep are typically febrile ($>40.5^{\circ}\text{C}$ [104.9°F]). The mucous membranes are congested, and there may be evidence of dehydration with sunken eyes and extended skin tent duration. Auscultation often does not reveal significant changes other than an increased respiratory rate. Rumen contractions are reduced or absent. There may be evidence of diarrhea. Frothy fluid may be noted around the mouth during the terminal stages.

Lesions: There are subcutaneous ecchymotic hemorrhages over the throat and ribs. The lungs are heavy, swollen, and purple-red in peracute cases, and the airways contain blood-stained froth. Cases of longer duration show anteroventral consolidation and fibrinous pleurisy.

Diagnosis: At necropsy, testing whether lung tissue sinks (pneumonia) or floats (normal) remains a useful screening test. In acute cases, cultures obtained from tracheal swabs or washes or from lung tissue or associated lymph nodes are diagnostic. Histopathologic examination is useful, especially if other types of pneumonia (eg, retrovirus interstitial pneumonia in adult sheep and goats) are also suspected. In chronic cases, bacterial cultures may be less rewarding; *Pasteurella* or *Mannheimia* may have been the initial problem, but results of cultures taken later may reveal

Trueperella pyogenes, a common causative agent of lung abscesses.

Treatment and Control: Whenever possible, treatment should be based on bacterial culture and sensitivity, especially in herd or flock outbreaks, when valuable animals are involved, or in acute or chronic cases when initial therapeutic attempts have failed. Commonly recommended antibiotics include oxytetracycline (10 mg/kg/day of non-long-acting product, or 20 mg/kg once of the long-acting product), florfenicol (20 mg/kg, every 48 hr), and tylosin (10–20 mg/kg, once to twice daily). Therapy should continue for at least 24–48 hr after body temperature has returned to normal. Duration of treatment usually is 4–5 days. Tilmicosin and other macrolide antibiotics can also be used but are considerably more expensive than oxytetracycline. Acute cases may also benefit from the use of NSAIDs (eg, flunixin meglumine or ketoprofen) in conjunction with antibiotic therapy for control of endotoxemia and inflammation.

Inadequate ventilation, crowding, commingling of animals from various farms (feedlot or sale barn situations), poor nutrition, failure of passive transfer of antibodies, transportation, and other stresses have all been associated with pneumonia outbreaks. Control and prevention lies with correction of the predisposing factors whenever practical.

Prevention of pasteurellosis is best attempted using vaccines incorporating iron-regulated proteins; because these proteins are antigenically similar, they confer cross-protection against other serotypes. Breeding ewes require a primary course of two injections 4–6 wk apart followed by an annual booster 4–6 wk before lambing. However, this vaccination regimen provides only passive immunity to the lambs for up to 5 wk. Lambs can be protected by two doses of vaccine administered from 10 days of age, because colostral antibody does not interfere with development of active immunity.

PROGRESSIVE PNEUMONIA

(Maedi, Zwoegersiekte, La bouhite, Graaff-Reinet disease)

Ovine progressive pneumonia and maedi-visna are chronic diseases of sheep caused by lentiviruses (family Retroviridae) that are structurally and antigenically similar. Progressive pneumonia virus and

maedi (meaning "dyspnea") virus induce chronic progressive pneumonias that present with similar clinical signs. Visna (meaning "wasting") is the term used in many parts of the world to refer to the neurologic form of the disease in sheep, resulting initially in unilateral pelvic paresis, progressing to paralysis. A closely related lentivirus-induced disease in goats, caprine arthritis and encephalitis (CAE, *see* p 747), affects the nervous system and joints. Reported seroprevalence for lentiviral infection in sheep varies widely, ranging from 49% in the western USA to 9% in the north Atlantic region. This variation has been reported in other countries as well and may result from varied climatic conditions (arid vs more lush climates) and management (range conditions vs close confinement).

Etiology and Pathogenesis: The causal lentivirus, which persists in lymphocytes, monocytes, and macrophages of infected sheep in the presence of a humoral and cell-mediated immune response, can be detected by several serologic tests. Seropositive sheep and goats must be considered infected and capable of transmitting the virus. Transmission occurs most commonly via the oral route, usually by ingestion of colostrum or milk that contains virus, or by inhalation of infected aerosol droplets. Intrauterine infection is thought to occur infrequently. All breeds of sheep and goats appear susceptible; however, some resistance to lentivirus infection may exist within breeds. Management practices can influence morbidity rates.

Clinical Findings: Signs rarely occur in sheep <2 yr old and are most common in sheep >4 yr old. The disease progresses slowly, with wasting and increasing respiratory distress as the main signs. Coughing, bronchial exudate, depression, and fever are seldom evident unless secondary bacterial infection occurs. A noninflammatory, indurative mastitis may occur. The encephalitic form of visna causes head tilt and circling, whereas the spinal form causes unilateral pelvic limb proprioceptive deficits progressing to paresis and eventually to complete paralysis.

Lesions: Macroscopic lesions of progressive pneumonia are confined to the lungs and associated lymph nodes. The lungs do not collapse when the thorax (with obvious rib indentations) is opened

and are abnormally firm and heavy (~2 kg; 2–4 times normal weight). Early lung changes may be difficult to detect, but later in the disease, lungs are mottled by gray and brown areas of consolidation. The mediastinal and tracheobronchial lymph nodes are greatly enlarged and edematous. Interstitial pneumonia, perivascular and peribronchial lymphoid hyperplasia, and hypertrophy of smooth muscle are seen throughout the entire lung. CNS lesions, when they occur, are those of meningoencephalitis with secondary demyelination. All lesions are progressive and result from the cellular immune response of the host, and not directly from viral damage.

Diagnosis: Differential diagnoses of progressive pneumonia include pulmonary adenocarcinoma, pleural abscesses, and pulmonary caseous lymphadenitis. Ultrasonographic examination is very useful to differentiate these various types of pneumonias in the live animal. Listeriosis, scrapie, cerebrosplinal nematodiasis, and space-occupying lesions should be considered when the neurologic form (visna) of the disease is seen.

In the live animal, agar gel immunodiffusion and ELISA tests are used. The competitive inhibition ELISA is reported to be highly sensitive and specific; it has been reported to produce false-negative results in animals very recently infected. Serologic testing is considered a useful tool to detect infected sheep, especially if the disease has been confirmed in the flock by histopathologic examination or virus isolation. PCR and virus isolation are sensitive and specific techniques to detect virus. However, both are more expensive and time consuming than serologic testing.

Control: Currently, there is no practical, effective treatment, and no vaccines are available. Therefore, the only means for control and prevention is serologic testing and removal of positive animals. Because of the long incubation period and time to seroconversion, retesting animals once a year, or even twice a year, is recommended. In addition to the test and cull approach, consideration should be given to raising neonates in isolation from their dams, especially if the dam is seropositive. Lambs should be fed colostrum from seronegative sheep, or heat-treated sheep colostrum, and raised on milk replacer, milk from seronegative ewes, or heat-treated sheep milk.

OVINE PULMONARY ADENOCARCINOMA

(Jaagsiekte, Sheep pulmonary adenomatosis)

Ovine pulmonary adenocarcinoma (OPA) is a contagious, viral, neoplastic disease of the lungs of sheep and more rarely of goats. It has been reported from Europe, Asia, Africa, and South and North America.

Etiology: OPA is an infectious neoplastic lung disease resulting from infection with a beta retrovirus called Jaagsiekte sheep retrovirus (JSRV). The virus replicates predominantly in the tumor cells, is released into the airways, and is found in respiratory secretions. Transmission of JSRV occurs predominantly through the aerosol route by inhalation of infected respiratory secretions, although the virus may also be transmitted via colostrum and milk.

Clinical Findings: The period of incubation after natural infection extends over months, so clinical signs generally become evident when sheep are 2–4 yr old. However, disease may be seen in lambs 8–12 mo old that are progeny of infected dams. The tumors produce clinical signs when they become sufficiently large or numerous enough to interfere with respiration. Affected sheep lose weight and show increasing respiratory distress and panting. Crackles are audible over a much larger area than the distribution of OPA lesions determined ultrasonographically. Coughing is not prominent, and infected animals are afebrile unless secondary infection develops. During the advanced stages of clinical disease, the tumor mass may occupy up to 60% of lung parenchyma. Clinical disease ends in death after many months but sometimes within 1–2 days due to secondary pasteurellosis.

Lesions: Tumors are confined to the lungs and, rarely, the associated lymph nodes. They vary from small nodules to extensive solid areas that involve the ventral parts of one or more lobes and are firm, gray, flat, and sharply demarcated. Copious amounts of white, frothy fluid are present in the air passages. Histologic changes are caused by uncontrolled proliferation of columnar-shaped type II pneumocytes and similar cells in the bronchioles (Clara cells).

Diagnosis: Chronic weight loss, dyspnea, crackles, and copious amounts of serous nasal discharge from accumulated lung fluid

in an adult sheep that is afebrile are highly suggestive clinical signs of OPA.

During the advanced stages of clinical disease, several mL of a clear, frothy fluid may flow freely from both nostrils when the sheep's head is lowered during feeding; this quantity may exceed 50 mL if the hindquarters are raised when the head is simultaneously lowered (colloquially referred to as the "wheelbarrow test"). This test causes affected sheep considerable distress and must be discontinued as soon as some clear fluid appears at the nostrils; euthanasia is warranted immediately once this positive result is obtained. Not all cases of OPA produce this fluid in detectable amounts even in the advanced stages of disease. Therefore, a negative wheelbarrow test should not be considered conclusive, although a positive wheelbarrow test is pathognomonic for OPA.

There is presently no commercial confirmatory serologic test for OPA. The PCR test has been used in research on OPA for several years. However, whereas the test is highly sensitive in laboratory assays, it fails to detect JSRV in most infected sheep other than overt clinical cases. This is because there are few infected cells in the blood during the early stages of disease progression. Bronchoalveolar lavage has been used on sedated sheep to collect cells from the airways, followed by DNA extraction and PCR testing. Although this method appears to offer better sensitivity than the blood test, the sample collection method does not lend itself to routine on-farm large-scale testing.

Ultrasonography can be used to differentiate chronic lung pathologies and support a diagnosis of OPA, including superficial lung lesions as small as 1–2 cm in diameter. The first indication of changes in the superficial lung parenchyma caused by OPA is the abrupt loss of the bright linear echo formed by normal aerated lung tissue (visceral or pulmonary pleura) to be replaced by a hypoechoic area in the ventral margins of the lung lobes at the fifth or sixth intercostal spaces.

Control: No specific treatment or vaccine is available. Affected sheep must be culled as soon as clinical suspicions are confirmed by ultrasonographic examination of the chest. Antibiotic therapy may temporarily improve the clinical appearance of those sheep with significant secondary bacterial infection. Good biosecurity is essential to minimize the risks of introducing OPA to unaffected

farms with purchased sheep. At this time, the best that can be recommended once a diagnosis is confirmed is removal of all animals showing signs suggestive of pulmonary adenomatosis. However,

subclinically infected sheep serve as a reservoir for the virus. Maintaining sheep in single-age groups is the most important management factor to reduce clinical disease.

RESPIRATORY DISEASES OF SMALL ANIMALS

Respiratory diseases are common in dogs and cats. Although clinical signs such as coughing and dyspnea are commonly referable to primary problems of the respiratory tract, they may also occur secondary to disorders of other organ systems (eg, congestive heart failure).

Both young and aged animals are at increased risk of developing respiratory disease. At birth, the respiratory and immune systems are incompletely developed; this facilitates the introduction and spread of pathogens within the lungs, and alveolar flooding may occur. In aged animals, chronic degenerative changes that disrupt normal mucociliary clearance and immunologic anergy may render the lungs more vulnerable to airborne pathogens and toxic particulates.

A varying flora of indigenous commensal organisms (including *Pasteurella multocida*, *Bordetella bronchiseptica*, streptococci, staphylococci, pseudomonads, and coliform bacteria) normally reside in the canine and feline nasal passages, nasopharynx, and upper trachea, and at least intermittently in the lungs, without causing clinical signs. Opportunistic infections by these bacteria may occur when respiratory defense mechanisms are compromised by infection with a primary pathogen (eg, distemper, parainfluenza virus, or canine type 2 adenovirus in dogs, and rhinotracheitis virus or calicivirus in cats), other insults (eg, inhalation of smoke or noxious gases), or diseases such as congestive heart failure and pulmonary neoplasia. Secondary bacterial infections complicate the management of viral respiratory infections of both dogs and cats. Pathogens may continue to reside in the respiratory tract of convalescent animals. When stressed, these animals may relapse; they can also act as a source of infection for others. Poor management practices

(eg, overcrowding) are often associated with poor hygienic and environmental conditions, and the resultant stress increases both the incidence and severity of infections. Conditions that favor the spread of infections often occur in catteries, kennels, pet shops, boarding facilities, and humane shelters.

Congenital abnormalities, such as stenotic nares, elongation of the soft palate, nasopharyngeal turbinates, and tracheal stenosis, can cause respiratory dysfunction. Neoplastic masses, degenerative changes of the airways, and tracheal collapse can result in dyspnea and other clinical manifestations of respiratory disease.

Tracheal collapse is most common in toy and miniature breeds of dogs and rare in cats. The cause is unknown. Affected animals have a nonproductive, honking, chronic cough and inspiratory or expiratory dyspnea. Frequently they are obese and may have concurrent cardiovascular or other pulmonary disease (especially chronic bronchitis). Weight loss (if obese) is critical in management. Other measures include exercise restriction, reduction of excitement and stress, and medical therapy, eg, antitussives, antibiotics, bronchodilators, and corticosteroids.

ALLERGIC PNEUMONITIS

Allergic pneumonitis is an acute or chronic hypersensitivity reaction of the lungs and small airways.

Etiology: An underlying cause is rarely determined in pulmonary hypersensitivity reactions in dogs and cats. Type I or immediate hypersensitivity is probably the most common mechanism, although Type III and IV mechanisms may also be involved (see IMMUNOLOGIC DISEASES, p 817 et seq). The cellular infiltrate is typically eosinophilic; however, mixed inflammatory infiltrates

consisting of mononuclear cells, eosinophils, and neutrophils, or predominantly lymphocytic infiltrates can be seen.

Eosinophilic bronchopneumopathy (formerly pulmonary infiltration with eosinophilia [PIE], see p 825) is a group of diseases associated with both pulmonary-associated and peripheral eosinophilia. Not all types of allergic pneumonitis, however, are associated with eosinophilic bronchopneumopathy. Causes of eosinophilic bronchopneumopathy include migrating parasites, reaction to microfilariae of heartworms, lungworms, chronic bacterial or fungal infections (eg, histoplasmosis, aspergillosis), viruses, external antigens, and unknown precipitating factors. Canine heartworm (see p 127) pneumonitis occurs when dogs become sensitized to microfilariae. A similar reaction may be seen in cats with heartworms. Migrating intestinal parasites and primary lung parasites may induce either subclinical or mild signs of allergic pneumonitis.

Pulmonary nodular eosinophilic granulomatous syndrome is a rare, severe eosinophilic bronchopneumopathy-like syndrome that occurs in dogs and is most often associated with heartworm infection or possibly an uncontrollable progressive form of eosinophilic bronchopneumopathy. In this condition, a severe granulomatous hypersensitivity reaction to microfilariae (or other antigen) results in mixed alveolar and interstitial pulmonary infiltrates plus variably sized, multiple pulmonary nodules scattered throughout the lung fields. Associated pathology may include eosinophilic granulomatous lymphadenitis, tracheitis, tonsillitis, splenitis, enteritis, gastritis, and pericholangitis. Pulmonary hypersensitivity also may be caused by drugs and reactions to inhaled allergens; however, this is poorly documented in small animals.

Clinical Findings: Chronic cough is the most common sign. It may be mild or severe, productive or nonproductive, and progressive or nonprogressive. Weight loss, tachypnea, dyspnea, wheezing, exercise intolerance, and occasionally hemoptysis may be seen. Severely affected animals may exhibit moderate to severe dyspnea and cyanosis at rest. Auscultation varies from unremarkable to increased breath sounds, crackles, or wheezes. Fever is usually absent. The degree of dyspnea and coughing is related to the severity of inflammation within the airways and alveoli.

Diagnosis: This is based largely on history and on radiographic and clinicopathologic findings. Thoracic radiographs frequently show irregular patchy alveolar infiltrates and increased bronchial and interstitial markings. Radiographic evidence of heartworm disease or parasitic pulmonary disease may suggest an underlying cause. Typical hematologic changes are mild leukocytosis, variable peripheral eosinophilia (4%–50%), and occasionally basophilia. Fecal analysis and an occult heartworm test are indicated when lung parasitism or heartworm disease is suspected. Bronchoalveolar lavage for cytologic analysis, culture, and detection of larval forms is often helpful. In allergic pneumonitis, bronchoalveolar lavage cytology generally reveals a predominance of eosinophils. Bacterial cultures of aseptically collected lavage specimens are commonly negative.

Treatment: When an underlying cause can be found, elimination of the offending agent and a short-term course of glucocorticoids resolves the problem. Prednisolone beginning at 1–2 mg/kg, PO, tapered over 10–14 days is often sufficient. When eosinophilic bronchopneumopathy is secondary to heartworm disease or pulmonary parasites, treatment with prednisolone before or during treatment for the parasite controls the pulmonary signs. When an underlying cause cannot be determined, prolonged therapy with prednisolone for 3–12 wk is often required. When severe bronchoconstriction is suspected, bronchodilators or β_2 -agonists may be helpful. Severely dyspneic animals may require short-term oxygen therapy.

CANINE INFLUENZA (FLU)

Etiology, Epidemiology, and

Transmission: Two strains of the canine influenza virus (CIV) have been identified, H3N8 and H3N2. The H3N8 strain was first identified in the USA in 2004, and the H3N2 strain was identified only in Asia until 2015, when an outbreak occurred in the USA. Outbreaks are most common when dogs are in close contact, eg, kennels, shelters, dog parks.

CIV is spread via respiratory secretions, contaminated objects (eg, water bowls), and people moving between infected and uninfected dogs. The incubation period is usually 2–4 days from exposure to onset of clinical signs, when dogs are most contagious; ~20% of infected dogs remain asymptomatic but can still shed virus.

Clinical Findings and Diagnosis: Most exposed dogs (80%) develop mild infection, with a cough that persists 1-3 wk and may be similar to the cough of canine infectious tracheobronchitis (see p 1491). Other possible clinical signs include ocular and nasal discharge, sneezing, fever, lethargy, and anorexia. Some dogs become severely ill, with high fever (104°-106°F), pneumonia, and secondary bacterial infection. The mortality rate is <10%.

There is no rapid test for specific diagnosis. Nasal or pharyngeal swabs from dogs ill for <3 days can be submitted for PCR testing. After 4 days of illness, PCR testing may result in false-negatives, because the time of maximal virus shedding has passed. Serum antibodies to CIV may be detected as early as 7 days after onset of clinical signs. The best method for confirmation of infection is serologic testing with acute and convalescent serum samples.

Treatment, Prevention, and Control:

Treatment is largely supportive; most dogs recover in 2-3 wk. Additional treatment (eg, antimicrobials, NSAIDs) is warranted to combat secondary bacterial infection, pneumonia, and other complications.

H3N8 canine influenza vaccines are available, but whether they protect against the H3N2 strain is unknown. Two vaccines for H3N2 canine influenza are available under conditional license from the USDA.

Routine infection control practices and good hygiene within facilities are key to preventing spread. CIV can persist in the environment for 1-2 days but is readily killed by common disinfectants. There is no evidence of transmission of CIV from dogs to people.

CANINE NASAL MITES

The canine nasal mite, also known as *Pneumonyssoides caninum* or *Pneumonyssus caninum*, has been reported worldwide, including the USA, Canada, Japan, Australia, South Africa, Italy, France, Spain, Norway, Sweden, Finland, Denmark, and Iran.

Etiology and Epidemiology: The canine nasal mite has most commonly been reported in dogs and has also been reported in a silver fox. There does not seem to be a breed, age, or sex predilection, although one report suggested that dogs >3 yr old were affected more often and that large-breed dogs had a higher incidence than small-breed dogs.

The mites live in the nasal passages and paranasal sinuses. The complete life cycle of *P. caninum* is not known or understood. Transmission is thought to be via direct and indirect contact between dogs. There is no evidence to suggest that *P. caninum* presents a zoonotic risk.

Clinical Findings: The most common clinical signs associated with nasal mite infestation include epistaxis, sneezing, reverse sneezing, impaired scenting ability, facial pruritus, nasal discharge, head shaking, and stridor. Other reported clinical signs include coughing, restlessness, and collapse. These signs are not specific for nasal mite infection and may indicate many types of upper respiratory disease.

Diagnosis: Differential diagnoses based on the clinical signs include many upper respiratory diseases such as rhinitis (idiopathic, secondary bacterial, parasitic, or fungal), oronasal neoplasia, dental disease (ornasal fistula), nasal foreign body, or nasopharyngeal disease (foreign body or mass lesions). To exclude concurrent systemic disease, a CBC, serum chemistry profile, and urinalysis should be performed. If epistaxis is present, a one-stage prothrombin time, partial thromboplastin time, and buccal mucosal bleeding time should be considered in addition to a platelet count.

Imaging of the nasal chambers via nasal/dental radiographs should be considered. Alternative imaging modalities such as CT provide excellent images of the nasal cavity and paranasal sinuses. More invasive diagnostic procedures such as rhinoscopy, retroflex nasopharyngoscopy, nasal flushing, and nasal biopsy must be delayed until after imaging, because iatrogenic changes may be hard to distinguish from primary disease.

Rhinoscopy and nasal flushing are the most useful diagnostic tools. Flexible rhinoscopes allow observation of the nasal choanae. This area is best visualized by putting a u-bend in the rhinoscope (retroflexed view) and advancing it into the oral cavity until it can be hooked under the soft palate. Gentle traction is applied, and the endoscopist can view the nasal choanae or the caudal nasal passages as they enter the nasopharynx. Flooding the nasal chambers with anesthetic gas or oxygen to encourage the mites to migrate toward the nasopharynx and the endoscope has been described.

Nasal flushing may also help identify *P. caninum*. This is generally performed with the dog under general anesthesia with a cuffed endotracheal tube in place. The

oropharynx is packed with gauze, and saline is flushed through the external nares with a Foley catheter or a tight-fitting syringe to collect fluid from the oropharynx. Retrograde flushing can be done by placing a modified catheter behind the soft palate, occluding the nasal pharynx, and flushing with saline. This allows fluid to be collected via the external nares. In both cases, the fluid should be evaluated using an illuminated magnifying lens to look for mites.

The definitive diagnosis of nasal acariasis can be made via endoscopy or nasal flushing if the mites are identified. This does not, however, determine whether the disease is primary or secondary.

Treatment: No drugs are currently approved for the treatment of *P caninum*; however, ivermectin (200–400 mcg/kg, SC or PO), milbemycin oxime (1 mg/kg, PO, three times at 10-day intervals), and selamectin (topical) have been suggested. The optimal treatment regimen has yet to be determined. Treatment has been reported to be effective in >85% of cases, and the prognosis is excellent. However, treatment may not completely eliminate clinical signs, particularly if infection is suspected rather than demonstrated. In these cases, it is probable that the signs are the result of a concurrent upper airway disease. Treatment is based on definitive diagnosis, but empirical therapy has also been performed based on a high index of suspicion.

FELINE RESPIRATORY DISEASE COMPLEX

Feline respiratory disease complex includes those illnesses typified by rhinosinusitis, conjunctivitis, lacrimation, salivation, and oral ulcerations. The principal diseases, feline viral rhinotracheitis (FVR; feline herpesvirus type 1), feline calicivirus (FCV), *Chlamydia felis*, *Mycoplasma felis*, or combinations of these infections, affect exotic as well as domestic species. Feline pneumonitis (*Chlamydia psittaci*) and mycoplasmal infections appear to be of lesser importance. Feline infectious peritonitis (see p 780) typically causes a more generalized condition but may cause signs of mild upper respiratory tract infection.

FVR and caliciviruses are host-specific and pose no known human risk. Human conjunctivitis caused by the feline chlamydial agent has been reported.

Etiology: Most acute feline upper respiratory infections are caused by FVR virus, although FCV may be more prevalent

in some populations. Dual infections with these viruses may occur. Other organisms such as *C felis*, *Mycoplasma* spp, and reoviruses are believed to account for most of the remaining infections or further complicate FVR or FCV infection. Concurrent *Bartonella henselae* also may further complicate infection.

Natural transmission of these agents occurs via aerosol droplets and fomites, which can be carried to a susceptible cat by a handler. Convalescent cats may harbor virus for many months. Calicivirus is shed continually, while infectious FVR virus is released intermittently. Stress may precipitate a secondary course of illness. The incubation period is 2–6 days for FVR and FCV, and 5–10 days for pneumonitis.

Clinical Findings: The onset of FVR is marked by fever, frequent sneezing, conjunctivitis, rhinitis, and often salivation. Excitement or movement may induce sneezing. The fever may reach 105°F (40.5°C) but subsides and tends to fluctuate from normal to 103°F (39°C). Initially, a serous nasal and ocular discharge occurs; it soon becomes mucopurulent and copious, at which time depression and anorexia are evident. Severely debilitated cats may develop ulcerative stomatitis, and ulcerative keratitis develops in some. Signs may persist for 5–10 days in milder cases and as long as 6 wk in severe cases. Generally, the mortality is low and prognosis good except for young kittens and aged cats. The illness often is prolonged, and weight loss may be marked. FVR often is complicated by secondary bacterial infections; abortions and generalized infections also have been associated with disease.

There are many serologically related strains of feline caliciviruses. They appear to have a predilection for the epithelium of the oral cavity and the deep tissues of the lungs. Some caliciviruses are non-pathogenic. Some induce little more than salivation and ulceration of the tongue, hard palate, or nostrils; others produce pulmonary edema and interstitial pneumonia. Clinically, it is often impossible to differentiate FVR from FCV infection. Two strains may produce a transient “limping syndrome” without signs of oral ulceration or pneumonia. These strains produce a transient fever, alternating leg lameness, and pain on palpation of affected joints. Signs occur most often in 8- to 12-wk-old kittens and usually resolve without treatment. The syndrome may occur in kittens vaccinated against FCV; no vaccine protects against both of the strains that produce the “limping syndrome.”

Calicivirus has also been found in cats with lymphocytic-plasmacytic gingivitis and stomatitis (see p 217). The superficial lesions heal rapidly, and appetite returns 2–3 days after onset. The clinical course usually is 7–10 days. An acute febrile response, inappetence, and depression are common signs. Serous rhinitis and conjunctivitis also can occur.

C. felis infections characteristically produce conjunctivitis (see p 506); infected cats sneeze occasionally. Fever may develop as the disease progresses beyond serous lacrimal discharge to mucopurulent conjunctivitis, lymphoid infiltration, and epithelial hyperplasia. Convalescent cats may undergo relapses.

Mycoplasma spp may infect the eyes and upper respiratory passages, characteristically producing severe edema of the conjunctiva and a less severe rhinitis.

The occurrence of severe viral upper respiratory disease is rare in adult, properly vaccinated cats. These cats should be tested for other upper respiratory diseases and, less commonly, concurrent immunodeficiency diseases, including feline leukemia virus and feline immunodeficiency virus.

Lesions: Lesions generally are confined to the respiratory tract, conjunctivae, and oral cavity. In FVR, the conjunctivae and nasal mucous membranes are reddened, swollen, and covered with a serous to purulent exudate. In severe cases, focal necrosis of these membranes may be seen. The larynx and trachea may be mildly inflamed. The lungs may be congested, with small areas of consolidation; however, pulmonary changes are rarely remarkable in FVR except possibly in stressed, young kittens. The characteristic histologic lesion of FVR is the acidophilic intranuclear inclusion body. During the early stage of illness, inclusions may be present in sites of epithelial necrosis on the tongue, nasal membranes, tonsils, epiglottis, trachea, and nictitating membranes. Inclusion bodies are transitory. Inclusions are not seen in calicivirus infections.

The characteristic lesion caused by FCV is ulceration of the oral mucosa. Lesions on the tongue or hard palate initially may appear as vesicles, which subsequently rupture. Ulcerations are occasionally found on the epithelium covering the median nasal septum. The more virulent caliciviruses destroy epithelial cells of the bronchioles and alveoli, which causes acute pulmonary edema that progresses through seropurulent bronchiolar hyperplasia and interstitial pneumonia.

Early in the clinical course of feline pneumonitis, the causative organism may be identified in Giemsa-stained conjunctival smears or scrapings. The elementary bodies are intracytoplasmic. Mycoplasmas occur as extracellular coccoid bodies often seen on the surface of conjunctival epithelial cells.

Diagnosis: The presumptive diagnosis is based on such typical signs as sneezing, conjunctivitis, rhinitis, lacrimation, salivation, oral ulcers, and dyspnea. FVR tends to affect the conjunctivae and nasal passages, caliciviruses the oral mucosa and lower respiratory tract. Chlamydial infections result in chronic, low-grade conjunctivitis. These characteristics may be obscured in mixed infections. Cytologic examination of Giemsa-stained conjunctival scrapings is of value for the identification of chlamydiae and mycoplasmas. A definitive diagnosis is based on isolation and identification of the agent. The oropharyngeal mucosa, external nares, and conjunctival sacs are the preferred sampling sites. However, diagnosis of FVR may be difficult, because virus is shed intermittently and because seroprevalence and virus isolation rates are similar in ill and clinically normal cats. Samples of ocular, nasal, or caudal pharyngeal secretions for PCR may help establish a diagnosis and causative agent.

Treatment: Treatment is largely symptomatic and supportive, but broad-spectrum antibiotics are useful against secondary bacterial invaders (eg, amoxicillin with clavulanic acid, cephalosporins, trimethoprim-sulfa, fluoroquinolones, tetracyclines, chloramphenicol) as well as directly against *C. felis* and *M. felis*. Tetracyclines and fluoroquinolones are the most effective against *C. felis* and *M. felis*. Nasal and ocular discharges should be removed frequently for the comfort of the cat. Nebulization or saline nose drops may aid in the removal of tenacious secretions. Nose drops containing a vasoconstrictor (eg, two drops of ephedrine sulfate [0.25% solution] in each nostril, bid) and antibiotics may help reduce the amount of nasal exudate. Prolonged use of nasal decongestants, however, may result in rebound nasal congestion and worsening of clinical signs. A bland ophthalmic ointment containing antibiotics (tetracyclines in *C. felis* infections) is indicated 5–6 times daily to prevent corneal irritation produced by dried exudate. If corneal ulcers develop in FVR infections (herpetic keratitis), ophthalmic preparations containing idoxuridine or acyclovir are indicated in addition to other antibiotic ophthalmic preparations. Lysine

(250 mg, PO, bid-tid) interferes with herpetic viral replication and may reduce the severity of FVR infection. If dyspnea is severe, the cat can be placed in an oxygen tent. Fluids may be indicated to correct dehydration, and force-feeding may be necessary. Esophagostomy and gavage may be appropriate for alimention in severely debilitated cats. Antihistamines (eg, chlorpheniramine maleate, PO, bid [8 mg for adults, 4 mg for kittens]) may be beneficial early in the course of the disease.

Prevention: Two types of modified-live virus FVR-FCV vaccines are available. The first type is intended for parenteral administration; cats >9 wk old should be vaccinated twice, with a 3-wk interval. Kittens should be vaccinated at intervals of 3–4 wk until they are ≥12 wk old. In adult cats, revaccination with a single dose every 1–3 yr is indicated.

The second type of vaccine is administered to healthy cats by instillation into the conjunctival cul de sacs and nasal passages. Owners should be advised that cats inoculated oronasally may sneeze frequently for 4–7 days after vaccination. Kittens vaccinated when <12 wk old should be revaccinated when reaching this age. Annual revaccination with a single dose is recommended.

Modified-live virus FVR-FCV vaccines intended for parenteral administration are available in combination with either chemically inactivated or modified-live virus feline panleukopenia vaccines. A parenterally administered vaccine composed entirely of inactivated viruses also is available.

Vaccines containing either chick-embryo- or cell-line-origin *C. felis* are administered parenterally. A single dose is recommended for cats >12 wk old; younger kittens should be revaccinated when they reach 16 wk. All should be revaccinated annually. These vaccines are indicated in catteries or on premises where *C. felis* infection has been confirmed. The chlamydial vaccines are available in combination with FVR-FCV and panleukopenia vaccines. Systematic vaccination and control of environmental factors (such as exposure to sick cats, overcrowding, and stress) provide good protection against upper respiratory disease.

LUNG FLUKES

Paragonimus kellicotti and *P. westermani* usually are found in cysts, primarily in the lungs of dogs, cats, and several other domestic and wild animals. They also have been found rarely in other viscera or the brain. Infection is most common in China,

southeast Asia, and North America. *P. westermani* is a parasite of people and other animals in China and other countries in the Far East.

The adult flukes are fleshy, reddish brown, oval, and ~14 × 7 mm. The eggs are golden brown, oval, distinctly operculated, and ~100 × 60 μm. The eggs pass through the cyst wall, are coughed up, swallowed, and passed in the feces. The life cycle includes several snails as the first intermediate host, and crayfish or crabs as the second. Dogs and cats become infected by eating raw crayfish or crabs that contain the encysted cercariae. After penetrating the intestinal wall and wandering in the peritoneal cavity, the young flukes pass through the diaphragm to the lungs, where they become established.

Infected animals may have a chronic, deep, intermittent cough and eventually become weak and lethargic, although many infections pass unnoticed. Finding the characteristic eggs in feces or sputum is diagnostic. The location in the lungs is ascertained by radiography. Aberrant infections can be identified serologically.

Fenbendazole (50 mg/kg/day, PO, for 10–14 days) or less preferably albendazole (25 mg/kg, PO, bid for 14 days) reduce the number of eggs deposited and eventually kill the parasites. Praziquantel (25 mg/kg, PO, tid for 3 days) may also eliminate lung flukes in dogs.

LUNG NEMATODES

See also LUNGWORM INFECTION, p 1421.

Aelurostrongylus abstrusus

Aelurostrongylus abstrusus, the most common lungworm of cats, is found in many parts of the world, including the USA, Europe, and Australia. They are small parasites (males 7 mm, females 10 mm), deeply embedded in the lung tissues. The eggs are forced into alveolar ducts and adjacent alveoli, where they form small nodules and hatch. Once the larvae escape, they are coughed up, swallowed, and passed in the feces. The larvae seen in the feces of infected animals are tightly coiled, have an undulating tail with a spine, and are <400 μm long. The life cycle includes snails or slugs as first intermediate hosts, and frogs, lizards, birds, or rodents as transport hosts of encysted larvae. When one of these transport hosts is eaten, the larvae migrate from the stomach to the lungs via the peritoneal and thoracic cavities. They reach

the lungs within 24 hr and are seen in the feces in ~1 mo.

Although prevalence can be high, clinical and diagnostic signs are often lacking. Chronic wasting, cough, dyspnea, and pulmonary wheezes may be seen. The lungs usually have solidified, gray, raised nodules 1–10 mm in diameter; generalized alveolar disease has been seen in chronic cases. Treatment is difficult and not often necessary, but fenbendazole (50 mg/kg/day, PO, for 10–14 days) or ivermectin (400 mcg/kg, SC, twice at a 3-wk interval) may be effective.

Capillaria aerophila

Although usually parasites of the frontal sinuses, trachea, bronchi, and rarely nasal cavities of foxes, *C. aerophila* are found in dogs and other carnivores. They are 25–35 mm long. The females produce eggs with bipolar plugs that resemble those of whipworms; however, their shells are colorless to greenish and pitted. The eggs are laid in the lungs, coughed up and swallowed, and passed in the feces. The eggs can be identified from either tracheal washes and bronchoalveolar lavage or fecal flotation. The life cycle is direct; dogs become infected through consumption of feed or water contaminated with larvated eggs. After hatching in the intestine, the larvae reach the lungs and bronchi via the circulatory system. They mature ~40 days after infection.

Clinical signs include coughing, sneezing, and nasal discharge. Treatment may be attempted using fenbendazole (50 mg/kg/day, PO, for 10–14 days) or ivermectin (200 mcg/kg, SC, twice at a 3-wk interval).

Filarids

Ostertus ostertus are tracheal worms of dogs, usually found in thin-walled nodules around the bronchial bifurcation. They have been found in the USA, South Africa, New Zealand, India, Great Britain, France, and Australia. The males are ~5 mm long, and the females 10–15 mm. The life cycle is direct, and an infected bitch can transfer larvae in her saliva to her pups while licking and cleaning them. On ingestion, the larvae pass to the blood and are carried to the lungs and bronchi.

A persistent, dry cough is the most common clinical sign. Coughing may later become severe, with respiratory distress. Finding larvae in the feces is diagnostic, but because these larvae are lethargic and few in number, bronchoscopy is a better method. Surgical excision of the nodules

combined with administration of fenbendazole, levamisole, or thiabendazole has effectively treated infected dogs. Chemotherapy alone can be successful but does not always result in a complete cure.

Filaroides hirthi is similar to *O. ostertus* but is found in the lung parenchyma. The females are oviparous. Adults are found in nests in the lung parenchyma, where a focal granulomatous reaction occurs. Diagnosis of low-grade infection can be difficult. Zinc sulfate flotation is usually more successful than using a Baermann apparatus. Treatment with fenbendazole (50 mg/kg/day, PO, for 10–14 days) or less preferably albendazole (25 mg/kg, PO, bid for 5 days and repeated in 2 wk) has reportedly been effective. Ivermectin (200 mcg/kg, SC, twice at a 3-wk interval) may also be effective.

NEOPLASIA

Tumors of the Nose and Paranasal Sinuses

Tumors of the nose and paranasal sinuses account for 1%–2% of all canine or feline tumors. The incidence in dogs is twice that in cats; incidence is also higher in males of both species than in females. The mean age at time of diagnosis is 9.5–10 yr for dogs and 12 yr for cats. In dogs, nasal tumors are nearly all malignant, and slightly >60% are carcinomas, of which adenocarcinoma is the most common. In dogs, the ethmoturbinate tend to be the site of predilection. Dolichocephalic and mesocephalic breeds appear to be at higher risk than brachycephalic breeds. In cats, ≥90% of nasal tumors are malignant, the most common being lymphoma and the second most common being carcinomas. Tumors of the nose and paranasal sinuses typically are very invasive locally and metastasize infrequently; metastasis is more likely in carcinomas and usually occurs late in the disease. Common sites of metastasis are regional lymph nodes, lungs, and brain. Invasion of the paranasal sinuses tends to be greater in dogs than in cats. In general, survival of untreated animals is 3–5 mo after diagnosis.

Chronic nasal discharge is the most common clinical finding; it may be mucoid, mucopurulent, or serosanguineous. Initially, discharge is unilateral but often becomes bilateral. Periodic sneezing, epistaxis, and respiratory stertor may occur. Facial and oral deformities result from destruction of bony or soft-tissue sinonasal structures. Retrobulbar extension of these tumors results in exophthalmos

and exposure keratitis. Secondary epiphora may occur if the nasolacrimal duct is blocked. Late in the disease, CNS signs (eg, disorientation, blindness, seizures, stupor, and coma) may develop if the tumor extends into the cranial vault.

Diagnosis is based on history and clinical findings and elimination of other causes of nasal discharge, sneezing, or facial deformation. Nasal radiographs or CT typically show increased density of the nasal cavity and frontal sinuses as well as evidence of bone destruction. CT is vastly superior to plain radiography in diagnosis of chronic nasal diseases. Definitive diagnosis is based on biopsy of tumor tissue, either with blind biopsy based on CT lesion localization or on rhinoscopic visualization with direct biopsy. Nasal hydropulsion using a high-pressure saline infusion into the nose often yields diagnostic samples and, if large volumes of tumor tissue break free, nasal obstruction will be relieved immediately.

Treatment largely depends on tumor type and extent of disease. The treatment of choice for canine nasal adenocarcinoma is radiation therapy. Aggressive surgical excision, chemotherapy, radiation therapy, or combinations for other tumor types afford a more favorable prognosis when diagnosis is made early.

Tumors of the Larynx and Trachea

Tumors of the larynx and trachea are rare in dogs and cats. Tumors of the larynx most frequently reported in dogs are oncocyoma, squamous cell carcinoma, mast cell tumor, melanoma, and osteosarcoma; in cats, they are squamous cell carcinoma, lymphosarcoma, and adenocarcinoma. Benign inflammatory polyps of the larynx also are seen in dogs and cats. Tumors of the trachea are particularly rare. Osteochondral dysplasia of the trachea (osteochondroma) is a benign tumor of the trachea primarily seen in dogs <1 yr old. Other benign mesenchymal tumors, carcinomas, and sarcomas are occasionally seen.

The most common signs of tumors of the larynx include inspiratory dyspnea, stridor, voice change (hoarse bark or loss of voice), coughing, and exertional dyspnea. Findings typically associated with tumors of the trachea are coughing, dyspnea, stridor, and rarely hemoptysis. Laryngeal and tracheal tumors may be associated with signs of fixed upper airway obstruction (inspiratory and expiratory dyspnea). The degree of dyspnea often relates to the degree of luminal obstruction.

Diagnosis is made from the history and clinical findings and by eliminating other causes of upper airway obstruction or coughing. The tumor mass may be seen radiographically or on laryngoscopy or tracheoscopy. Definitive diagnosis is made on biopsy.

Surgical excision and resection is the treatment of choice. Radiation therapy may be palliative for radiosensitive tumors such as squamous cell carcinoma, mast cell tumor, and lymphoma. Surgical resection of tracheal osteochondral dysplasia in dogs is curative.

Primary Lung Tumors

Primary lung tumors are rare in dogs and cats; however, the reported incidence of lung carcinomas has increased at least 100% during the last 20 yr. This is attributed to an increased average life span, better detection and awareness, or possibly increased exposure to environmental carcinogens. Most primary lung tumors are diagnosed at a mean age of 10–12 yr in dogs and 12 yr in cats. There is no consistent breed or sex predilection in either species. Primary lung tumors usually originate from the terminal bronchioles and alveoli; they occasionally develop as a second coincidental tumor, which may make differentiation between primary and metastatic disease difficult.

Of the primary lung tumors in dogs and cats, >80% are malignant. Adenocarcinoma and alveolar carcinoma are the most common types. Primary lung sarcomas and adenomas are rare in both species. Metastatic spread of primary lung tumors is generally to other areas of the lungs, tracheobronchial lymph nodes, bone, and brain. Intrapulmonary spread via the airways occurs in ~50% of dogs with adenocarcinoma. Metastatic spread to the pleurae, pericardium, heart, and diaphragm may occur; miscellaneous extrathoracic sites include liver, spleen, and kidney. Dogs with papillary (bronchoalveolar) adenocarcinoma have a better prognosis than those with other lung tumors; however, histologic grade and detection of clinical signs are the most important determinants of prognosis and survival. Both recurrence and metastasis tend to occur earlier and with greater frequency in dogs with moderately or poorly differentiated tumors.

Clinical Findings: Primary lung tumors have variable manifestations, which depend on the location of tumor, rapidity of tumor growth, presence of previous or concurrent pulmonary disease, and awareness of the

owner. Common signs include cough, inappetence, weight loss, reduced exercise tolerance, lethargy, tachypnea, dyspnea, wheezing, vomiting or regurgitation, pyrexia, and lameness. The most common clinical findings in dogs are cough, dyspnea, lethargy, and weight loss, although 25% of dogs with primary lung tumors have no clinical signs related to the tumor. Coughing is uncommon in cats; nonspecific signs, such as inappetence, weight loss, and tachypnea and dyspnea, are more common. In either species, tachypnea or dyspnea indicates massive tumor burden or pleural effusion. Pleural effusion is particularly common in cats with primary lung tumors. Lameness may be due to hypertrophic osteopathy (unusual in cats) or to metastasis to bone or skeletal muscle. Thoracic auscultation may be normal, reflect increased breath sounds compatible with pulmonary airway disease, or be muffled because of pulmonary consolidation or pleural effusion.

Diagnosis: One-third or more of primary lung tumors are recognized incidentally during radiography for other problems, or at necropsy. Thoracic radiographs are essential for a tentative diagnosis in those animals exhibiting compatible clinical signs. Primary lung tumors in dogs may occur as single or multiple circumscribed mass lesions, as a diffuse lung pattern, or as a lobar consolidation. In cats, single circumscribed mass lesions are less common, whereas a diffuse lung pattern or lobar consolidation is more frequent. Pleural fluid accumulation is common in cats and less frequent in dogs. In either species, chest wall involvement and hilar lymphadenopathy may be seen. Tentative diagnosis can be made by excluding other causes of pulmonary disease with similar radiographic lung patterns. Definitive diagnosis requires biopsy.

Treatment: Surgical resection of tumor via lobectomy of diseased lung lobes is the treatment of choice. Inoperable lesions or metastatic disease may be controlled with chemotherapy. Overall median survival time for dogs having surgical treatment for primary lung tumor is 120 days. Mean survival time for operable primary lung tumors without node involvement in dogs is 12 mo; if the lymph nodes are involved or multiple tumors are found at the time of diagnosis, survival time is only 2 mo. Recurrence or metastasis of tumor is a common cause of death.

Metastatic Tumors of the Lungs

A localized tumor may extend to the lungs by dissemination through hematogenous or lymphatic routes or by direct extension of tumor cells. Certain primary tumors, such as mammary adenocarcinoma, osteosarcoma, hemangiosarcoma, and oral melanoma, most commonly metastasize to the lungs. The lungs may be the only site of metastasis, or there may be concurrent metastasis in other organs; in the former, the diagnostic approach is to identify an occult primary tumor or to carefully review the medical history for disclosure of previous tumor removal. Because pulmonary metastasis occurs late in the clinical course of a malignant tumor, prognosis is poor.

The signs of metastatic pulmonary disease are similar to those of primary lung tumors except that coughing is less common. Severity of signs depends on the anatomic location of the tumor and whether the lesions are solitary or multiple.

Establishing a diagnosis is similar to that for primary lung tumors. Because of the limitations of routine radiography, small lesions (≤ 3 mm in diameter), which are present in $\geq 40\%$ of cases with pulmonary metastasis, may not be seen. Thoracic CT can identify lesions not seen radiographically.

Radiography of the chest should precede removal of tumors with a known high incidence of metastatic spread to the lungs. The major goal of cancer therapy is prevention of metastasis rather than cancer eradication. Slow-growing or solitary metastatic lesions are best treated by surgical excision. Chemotherapy or radiation therapy may be useful with certain tumor types not amenable to surgical resection. Overall, the prognosis for animals with pulmonary metastasis is poor.

PNEUMONIA

Pneumonia is an acute or chronic inflammation of the lungs and bronchi characterized by disturbance in respiration and hypoxemia and complicated by the systemic effects of associated toxins. The usual cause is primary viral infection of the lower respiratory tract.

Canine distemper virus, adenovirus types 1 and 2, parainfluenza virus, and feline calicivirus cause lesions in the distal airways and predispose to secondary bacterial invasion of the lungs. Parasitic invasion of the bronchi, as by *Filaroides*, *Aeluro-*

trongylus, or *Paragonimus* spp may result in pneumonia. Protozoan involvement, eg, by *Toxoplasma gondii* (see p 685) or *Pneumocystis jiroveci*, is rarely seen. Tuberculous pneumonia, although uncommon, is seen more often in dogs than in cats. The incidence of mycotic granulomatous pneumonias is also higher in dogs than in cats. Cryptococcal pneumonia has been described in cats. Injury to the bronchial mucosa and inhalation or aspiration of irritants may cause pneumonia directly and predispose to secondary bacterial invasion. Aspiration pneumonia (see p 1417) may result from persistent vomiting, abnormal esophageal motility, or improperly administered medications (eg, oil or barium) or food (forced feeding); it may also follow suckling in a neonate with a cleft palate.

Clinical Findings: The initial signs are usually those of the primary disease. Lethargy and anorexia are common. A deep cough is noted. Progressive dyspnea, “blowing” of the lips, and cyanosis may be evident, especially on exercise. Body temperature is increased moderately, and there may be leukocytosis. Auscultation usually reveals consolidation, which may be patchy but more commonly is diffuse. In the later stages of pneumonia, the increased lung density and peribronchial consolidation caused by the inflammatory process can be visualized radiographically. Complications such as pleuritis, mediastinitis, or invasion by opportunistic organisms may occur.

Diagnosis: Analysis of bronchoalveolar lavage fluid is valuable for the diagnosis of bacterial infections. Cytologic examination can demonstrate the animal's immune response and indicate the intracellular or extracellular location of bacteria. Bacterial culture and sensitivity testing is required and may include anaerobe and mycoplasma culture, especially in refractory cases. A viral etiology generally results in an initial body temperature of 104°–106°F (40°–41°C). Leukopenia, often expected, may not be seen in many viral respiratory infections (eg, canine infectious tracheobronchitis, feline calicivirus pneumonia, feline infectious peritonitis pneumonia). A history of recent anesthesia or severe vomiting indicates the possibility of aspiration pneumonia. Acutely affected animals may die within 24–48 hr of onset. Mycotic pneumonias are usually chronic in nature. Miliary nodules seen at necropsy may suggest protozoal pneumonia.

Treatment: The animal should be placed in a warm, dry environment. Anemia, if present, should be corrected. If cyanosis is severe, oxygen therapy may be used, administered by means of an oxygen cage, with a concentration of 30%–50%. Empirical antimicrobial chemotherapy should be initiated and changed if needed based on results of culture of bronchoalveolar lavage fluid. Supportive therapy should be instituted as needed and may include oxygen supplementation, pulmonary physiotherapy (nebulization and coupage), and bronchodilators. If no response is seen after 48–72 hr of therapy, the treatment plan should be reassessed. Antimicrobial chemotherapy should be continued 1 wk after clinical and radiographic signs resolve.

Animals should be reexamined frequently. Chest radiographs should be repeated at regular intervals to monitor recurrence or note a primary underlying disease process and to detect complications such as lung consolidation, atelectasis, or abscessation.

PULMONARY THROMBOEMBOLISM

See also THROMBOSIS, EMBOLISM, AND ANEURYSM, p 141.

Pulmonary thromboembolism (PTE) is an obstruction of one or more pulmonary vessels by a blood clot. The actual incidence of PTE is uncertain, although in critically ill animals or in those with certain disease states (eg, immune-mediated hemolytic anemia, corticosteroid administration, bacterial infections, protein-losing enteropathy or nephropathy, neoplasia, trauma, feline infectious peritonitis, diabetes mellitus, hyperadrenocorticism, hypothyroidism, disseminated intravascular coagulation, dirofilariasis) the incidence is considerable, and PTE is underdiagnosed. Mortality rates of PTE in animals are uncertain but probably significant. Survival depends on early diagnosis and early appropriate therapy.

Thromboemboli in the venous circulation become trapped in the pulmonary vasculature and, if occlusion is substantial, pulmonary and hemodynamic sequelae result. Animals with preexisting cardiac or respiratory compromise may be affected earlier or more severely. The acute pulmonary consequences of PTE include ventilation-perfusion mismatch, hypoxemia, hyperventilation, and bronchoconstriction. Hemodynamic consequences of PTE are related to the magnitude of the

obstruction and presence of coexisting cardiopulmonary disease. Myocardial ischemia, arrhythmias, or right ventricular failure may result. Decreased cardiac output may ensue with severe obstruction to pulmonary arterial blood flow as a result of decreased venous cardiac return.

In dogs, PTE is associated with protein-losing nephropathy, heartworm disease, endocarditis, cardiomyopathy, necrotizing pancreatitis, hypercortisolism, immune-mediated hemolytic anemia, sepsis, diabetes mellitus, neoplasia, atherosclerosis, trauma, and major surgical procedures. Cardiomyopathy and neoplasia are most commonly associated with PTE in cats.

Clinical Findings: Clinical signs are nonspecific and most often subclinical or may be mild to profound, reflecting the severity of cardiorespiratory compromise. Dyspnea, tachypnea, and depression are commonly seen. Coughing, cyanosis, hemoptysis, collapse, shock, and sudden death can occur.

Diagnosis: Diagnosis is often difficult because PTE can resemble many other conditions, including pneumonia, pulmonary edema or hemorrhage, neoplasia, or pleural effusion. Routine diagnostic tests such as thoracic radiography or arterial blood gas analysis are nonspecific and rarely confirm diagnosis. Arterial blood gas analysis will identify hypoxemia present in 80% of dogs, although response to oxygen is variable. Thoracic radiographs can be normal in 9%–27% of dogs and in 9% of cats with PTE. Abnormal radiographic findings with PTE include alveolar or interstitial pulmonary infiltrates or regional hypovascular lung areas. However, thoracic radiographs that underestimate the degree of clinical respiratory compromise should raise suspicion of PTE. Blood gas analysis may reveal hypoxemia and hypocapnia, indicating inefficient gas exchange, but the presence of normal blood gas values does not exclude PTE. Echocardiography can aid in assessment, demonstrating changes suggestive of PTE and pulmonary hypertension (dilation of the right ventricle, pulmonary artery, inferior vena cava; right ventricular hypokinesis; tricuspid regurgitation; abnormal septal wall motion). A normal echocardiogram does not exclude diagnosis of PTE. Spiral CT angiography or selective pulmonary angiography remain gold standards for diagnosis of PTE in people, but these advanced imaging studies are available at few veterinary institutions.

Treatment: Therapy should begin as soon as possible and include support of respiratory and cardiovascular systems, prevention of thrombus development and recurrence, and possibly thrombolysis. Oxygen supplementation and bronchodilators are indicated when dyspnea is evident or when arterial oxygen saturation is $<92\%$. Although anticoagulants such as warfarin or unfractionated or low-molecular-weight heparin do not lyse existing thrombi, their use is indicated to inhibit thrombus propagation and prevent recurrent venous thrombosis. Antiplatelet drugs such as aspirin or clopidogrel can be given together with, but not in lieu of, anticoagulant therapy. Sildenafil may benefit animals with documented pulmonary hypertension. Thrombolytic therapy can rapidly cause clot lysis and improve cardiovascular function and hemodynamic stability, thereby reducing mortality in animals with massive PTE and shock. Veterinary experience with thrombolytic agents such as streptokinase and tissue plasminogen activator is limited.

RHINITIS AND SINUSITIS

Inflammation of the mucous membranes of the nose and sinuses may be acute or chronic.

Etiology: Viral infection is the most common cause of acute rhinitis or sinusitis in dogs and cats. Feline viral rhinotracheitis (FVR), feline calicivirus (FCV), canine distemper, canine adenovirus types 1 and 2, and canine parainfluenza are most frequently incriminated. Chronic states exist for FVR and FCV, with intermittent shedding associated with stress. Bacterial rhinitis or sinusitis frequently is a secondary complication. Primary bacterial rhinitis is extremely rare in dogs. It may result from infection with *Bordetella bronchiseptica* in dogs. Bacterial rhinitis appears to be a common complicating factor in cats with chronic rhinosinusitis, although exposure to environmental aeroallergens may also play a role. Allergic rhinitis or sinusitis is a poorly defined atopy that may occur seasonally, possibly in association with pollen production, or perennially, probably in association with house dusts and molds. Smoke aspiration, inhalation of irritant gases and dusts, or foreign bodies lodged in the nasal passages also may cause acute rhinitis.

Chronic rhinitis is commonly complicated by secondary bacterial colonization or infection because the primary nasal

disease results in increased mucus production and altered mucociliary clearance of debris within the nose. Underlying causes of chronic rhinitis include idiopathic chronic inflammatory disease (lymphoplasmacytic rhinitis), trauma, parasites (*Cuterebra*), foreign bodies, neoplasia, or mycotic infection. In cats, chronic rhinosinusitis is a frequent sequela of acute viral infections of the nasal and sinus mucosa that result in hyperplastic glandular and epithelial changes. Rhinitis or sinusitis may result when an apical tooth root abscess extends into the maxillary recess. Mycotic rhinosinusitis may be caused by *Cryptococcus neoformans*, *Aspergillus* spp, and *Penicillium* spp. Cats are more often affected with *Cryptococcus* spp than dogs, whereas aspergillosis is frequent in dogs but rare in cats.

Clinical Findings: Acute rhinitis is characterized by nasal discharge, sneezing, pawing at the face, respiratory stertor, open-mouth breathing, and/or inspiratory dyspnea. Lacrimation and conjunctivitis often accompany inflammation of the upper respiratory passages. Affected tissues are often hyperemic and edematous. The nasal discharge is serous but becomes mucoid as a result of secondary bacterial infection. If inflammatory cells infiltrate the mucosa, the discharge may become mucopurulent. Sneezing, in an attempt to clear the upper airways of discharge or exudate, is seen most frequently in acute rhinitis and tends to be intermittent in chronic rhinitis. Aspiration reflex ("reverse sneeze"), a short paroxysmal episode of inspiratory effort in an attempt to clear the nasopharynx of obstructing material, may also be seen.

Respiratory stertor, open-mouth breathing, and inspiratory dyspnea occur when the nasal passages are narrowed from inflamed mucosa, glandular elements, and secretions. An acute unilateral nasal discharge, possibly accompanied by pawing at the face, suggests a foreign body. Neoplastic or mycotic disease is suggested by a chronic nasal discharge that was initially unilateral but becomes bilateral or that changes in character from mucopurulent to serosanguineous or hemorrhagic. Approximately 35% of cats with nasal cryptococcosis have facial deformity (dorsal lump) of the rostral aspect of the nose. Head shyness or facial pain is more commonly associated with fungal rhinitis in dogs.

Diagnosis: Diagnosis is based on history, physical examination, radiographic findings (especially CT), rhinoscopy, nasal biopsy,

deep nasal tissue culture, and elimination of other causes of nasal discharge and sneezing. Advanced imaging studies and biopsy may identify a specific etiologic diagnosis for nasal discharge (eg, fungal rhinitis, neoplasia, foreign body) in as few as 36% of cats and 63% of dogs with chronic nasal disease.

Serum titer for cryptococcal antigen is a very specific and sensitive test for nasal cryptococcosis. Serologic evaluation for aspergillosis is more problematic in that negative test results do not exclude infection. Nasal tissue culture for *Aspergillus* may also result in false-positive results; as many as 30% of normal dogs and 40% of dogs with nasal neoplasia have positive culture results. The combination of seropositivity for and culture identification of *Aspergillus* is highly suggestive of infection, although negative test results do not exclude nasal aspergillosis. Direct sampling of visualized suspected fungal plaques may potentially yield *Aspergillus* hyphae in all cases.

Treatment: In mild or acute cases, supportive treatment may be effective. Severe cases of rhinosinusitis in kittens or adult cats may require parenteral fluids to prevent dehydration, and nutritional support via a nasogastric tube to maintain weight. Chronic secondary bacterial rhinosinusitis may be treated with antimicrobial chemotherapy for 3–6 wk. Intermittent use of vasoconstrictive nasal decongestants usually provides only temporary relief of congestion.

Mycotic rhinosinusitis requires antifungal therapy based on identification of a fungal etiologic agent. Fluconazole (50–100 mg/day, PO) or itraconazole (50–100 mg/day, PO) may be effective for treatment of nasal cryptococcosis in cats. Oral antifungal agents have variable efficacy in treatment of dogs with nasal aspergillosis, although voriconazole (4 mg/kg, PO, bid) alone or in combination with terbinafine (15 mg/kg, PO, bid for 1 mo) may be effective. Topical intranasal infusions of enilconazole or clotrimazole or combined clotrimazole solution and cream depot therapy instilled via the frontal sinuses have success rates as high as 50% for the first treatment and 90% with two treatments, although reinfection or relapse may occur.

Animals that do not respond to medical therapy may require surgery consisting of sinusotomy or rhinotomy, lavage, and biopsy to reestablish definitive diagnosis. Radiation therapy is the most viable treatment for intranasal neoplasia.

TONSILLITIS

Etiology: Tonsillitis is common in dogs but rare in cats. In dogs, it seldom occurs as a primary disease, but when present it is most frequently seen in small breeds. It usually is secondary to nasal, oral, or pharyngeal disorders (eg, cleft palate); chronic vomiting or regurgitation (eg, from megaesophagus); or chronic coughing (eg, with bronchitis). Chronic tonsillitis may be seen in brachycephalic dogs in association with pharyngitis accompanying soft palate elongation and redundant pharyngeal mucosa. Chronic tonsillitis in young dogs is thought to represent maturation of pharyngeal defense mechanisms.

Escherichia coli, *Staphylococcus aureus*, and hemolytic streptococci are the pathogenic bacteria most often cultured from diseased tonsils. Plant fibers or other foreign bodies that lodge in the tonsillar fossa may produce a localized unilateral inflammation or a peritonsillar abscess. Other physical and chemical agents may cause irritation of the oropharynx and one or both tonsils. Tonsillitis may also accompany neoplastic tonsillar masses because of physical trauma or secondary bacterial infection.

Clinical Findings and Diagnosis:

Tonsillitis is not always accompanied by obvious clinical signs. Fever and malaise are uncommon unless consequent to systemic infection. Gagging, followed by retching or a short, soft cough, may result in expulsion of small amounts of mucus. Inappetence, listlessness, salivation, and dysphagia are seen in severe tonsillitis.

Tonsillar enlargement may range from protrusion just out of the crypts to a mass of sufficient size to cause dysphagia or inspiratory stridor. A septic, suppurative exudate may surround the tonsil, which may be reddened with small necrotic foci or plaques. Tonsillitis usually is a sign of generalized or regional inflammatory disease; therefore, primary tonsillitis should be diagnosed only after underlying diseases have been excluded. Squamous cell carcinoma, malignant melanoma, and lymphosarcoma are common in canine tonsils and should be distinguished from tonsillitis. Tonsillar lymphosarcoma generally results in bilateral symmetric enlargement, whereas nonlymphoid neoplasia is usually unilateral.

Treatment: Prompt systemic administration of antibiotics is indicated for bacterial tonsillitis. Penicillins are often effective, but

in refractory cases, culture and sensitivity testing may be needed. Mild analgesics are appropriate for severe pharyngeal irritation, and a soft, palatable diet is recommended for a few days until the dysphagia resolves. Parenteral administration of fluids is required for those animals unable to take food by mouth.

Tonsillectomy is rarely required for chronic primary tonsillitis but provides permanent relief. Other indications for tonsillectomy include tonsillar neoplasia and tonsillar enlargement that interferes with airflow (eg, in brachycephalic breeds).

TRACHEOBRONCHITIS

Tracheobronchitis is an acute or chronic inflammation of the trachea and bronchial airways; it may be primary or secondary depending on the etiologic agent. Bronchitis may extend from the bronchioles to the lung parenchyma.

Etiology: Canine infectious tracheobronchitis (kennel cough, *see* p 1491) is often secondary to viral infection of the respiratory system. Other causes of tracheobronchitis in dogs include parasites, eg, *Aelurostrongylus abstrusus* (also in cats), *Capillaria aerophila*, *Crenosoma vulpis*, and *Osleria osleri*.

Tracheitis may be secondary either to diseases of the oropharynx or to chronic coughing related to heart disease or noncardiac pulmonary disease. Other causes include smoke aspiration and exposure to noxious chemical fumes. Exacerbation of a chronic bronchitis affecting middle-aged and older dogs may follow sudden changes in the weather or other environmental stresses. Feline bronchial asthma (allergic bronchitis) is a syndrome in cats with similarities to asthma in people. Young cats and Siamese and Himalayan breeds are most affected. Feline asthma is associated with airway hyperresponsiveness, airflow obstruction, airway remodeling, and eosinophilic airway inflammation. Asthma in cats is induced by an aberrant immune response with upregulation of cytokines, leading to IgE production. Foreign bodies in the airway and developmental abnormalities such as laryngeal deformities may predispose to bronchitis. Chronic bronchitis most often affects small breeds of dogs, although it is also seen in large breeds. It is characterized by persistent cough for at least 2 mo in the absence of specific pulmonary disease. Bronchiectasis may occur as the end

stage of chronic bronchitis in dogs. Recognition of tracheobronchitis as an often secondary disease syndrome underlies the importance of diagnosis and control of an associated primary disease.

Clinical Findings: Spasms of coughing are the outstanding sign. These are most severe after rest or a change of environment or at the beginning of exercise. On auscultation, respiratory sounds may be essentially normal. In advanced cases, inspiratory crackles and expiratory wheezes are heard. Body temperature may be slightly increased. The acute stage of bronchitis passes in 2–3 days; the cough, however, may persist for 2–3 wk. Severe bronchitis and pneumonia are difficult to differentiate; the former often extends into the lung parenchyma and results in pneumonia. Feline bronchial asthma may result in cyanosis and dyspnea and may be accompanied by eosinophilia.

Lesions: During the acute and subacute inflammatory stages, the air passages are filled with frothy, serous, or mucopurulent exudate. In chronic bronchitis, they contain excessive viscid mucus. The epithelial linings are roughened and opaque, a result of diffuse fibrosis, edema, and mononuclear cell infiltration. There is hypertrophy and hyperplasia of the tracheobronchial mucous glands and goblet cells. The act of coughing is an attempt to remove the accumulations of mucus and exudate from the respiratory passages.

Diagnosis: The diagnosis is made from the history and clinical signs and by elimination of other causes of coughing. In chronic bronchitis, chest radiographs may show an increase in linear and peribronchial markings. Bronchoscopy reveals inflamed epithelium and often mucopurulent mucus in the bronchi. In addition, the procedure allows collection of biopsy and swab samples for *in vitro* assay. Bronchial washing is an additional diagnostic aid that may demonstrate causative agents or significant cellular responses (eg, eosinophils).

Treatment: In mild or acute cases, supportive therapy may be effective, but treatment of concurrent disease is also indicated. Rest, warmth, and proper hygiene are important. Broad-spectrum antimicrobial chemotherapy is indicated for treatment of cough when infection is documented. Corticosteroids are the mainstay of therapy to reduce airway

inflammation in dogs with chronic bronchitis. Persistent, nonproductive coughing is best controlled by antitussives that contain codeine. If conservative medical management is unsuccessful, laboratory tests and radiographs of the thorax and cervical trachea should be evaluated to eliminate other differential diagnoses. Bronchoalveolar lavage or transtracheal wash for cytology and culture sensitivity may be indicated to identify an etiologic agent and to determine appropriate antimicrobial chemotherapy. Pulmonary physiotherapy consisting of sodium chloride nebulization and gentle coughage may loosen secretions and stimulate expectoration. A bathroom environment with steam from a hot shower may be substituted for nebulization.

Oral (prednisolone, dexamethasone) or inhaled (fluticasone, budesonide) corticosteroids are indicated for treatment of feline asthma. Bronchodilators (albuterol, terbutaline) may be considered for adjunctive therapy in combination with glucocorticoids but not as sole therapy for feline asthma. Feline aerosol chambers and inhaler therapy are available for aerosol drug delivery in cats with feline asthma. Cyprohepatidine, an antiserotonergic drug, has been suggested; however, studies have failed to show significant reduction in eosinophilic airway inflammation. Experimental studies suggest that cyclosporine A therapy may hold promise to inhibit development of eosinophilic airway inflammation and airway remodeling through inhibition of T-cell activation and cytokine synthesis. Avoidance of environmental aeroallergens (eg, cigarette smoke, perfumes, pollens, molds, dust) must be considered in management of these cats.

Infectious Tracheobronchitis of Dogs

(Kennel cough)

Infectious tracheobronchitis results from inflammation of the upper airways. It is a mild, self-limiting disease but may progress to fatal bronchopneumonia in puppies or to chronic bronchitis in debilitated adult or aged dogs. The illness spreads rapidly among susceptible dogs housed in close confinement (eg, veterinary hospitals or kennels).

Etiology: Canine parainfluenza virus, canine adenovirus 2 (CAV-2), or canine distemper virus can be the primary or sole pathogen involved. Canine reoviruses (types 1, 2, and 3), canine herpesvirus,

and canine adenovirus 1 (CAV-1) are of questionable significance in this syndrome. *Bordetella bronchiseptica* may act as a primary pathogen, especially in dogs <6 mo old; however, it and other bacteria (usually gram-negative organisms such as *Pseudomonas* sp, *Escherichia coli*, and *Klebsiella pneumoniae*) may cause secondary infections after viral injury to the respiratory tract. Concurrent infections with several of these agents are common. The role of *Mycoplasma* sp has not been clearly established. Stress and extremes of ventilation, temperature, and humidity apparently increase susceptibility to, and severity of, the disease.

Clinical Findings: The prominent clinical sign is paroxysms of harsh, dry coughing, which may be followed by retching and gagging. The cough is easily induced by gentle palpation of the larynx or trachea. Affected dogs demonstrate few if any additional clinical signs except for partial anorexia. Body temperature and WBC counts usually remain normal. Development of more severe signs, including fever, purulent nasal discharge, depression, anorexia, and a productive cough, especially in puppies, indicates a complicating systemic infection such as distemper or bronchopneumonia. Stress, particularly due to adverse environmental conditions and improper nutrition, may contribute to a relapse during convalescence.

Diagnosis: Tracheobronchitis should be suspected whenever the characteristic cough suddenly develops 5–10 days after exposure to other susceptible or affected dogs. Severity usually diminishes during the first 5 days, but the disease persists for 10–20 days. Tracheal trauma secondary to intubation may produce a similar but generally less severe syndrome. Thoracic radiographs are essential to determine the severity of disease and to exclude other causes of cough.

Treatment: Preferably, affected dogs should not be hospitalized because the disease is usually highly contagious (and also self-limiting). Appropriate management practices, including good nutrition, hygiene,

and nursing care, as well as correction of predisposing environmental factors, hasten recovery. Cough suppressants containing codeine derivatives, such as hydrocodone (0.25 mg/kg, PO, bid-qid) or butorphanol (0.05–0.1 mg/kg, PO or SC, bid-qid), should be used only as needed to control persistent nonproductive coughing. Antibiotics are usually not needed except in severe chronic cases; cephalosporins, quinolones, chloramphenicol, and tetracycline are preferable because they reach effective concentrations in the tracheobronchial mucosa. When needed, the antibiotic should be selected by culture and sensitivity tests of specimens collected by transtracheal aspiration or bronchoscopy. Antibiotics given PO or IM may not significantly reduce the numbers of *B bronchiseptica* in the distal trachea or major bronchi. Thus, in severely affected dogs that are not responsive to parenteral antibiotics, kanamycin sulfate (250 mg) or gentamicin sulfate (50 mg) diluted in 3 mL of saline may be administered by aerosolization bid for 3 days. Aerosolization treatment should be preceded by administration of bronchodilators. Endotracheal injection of antibiotics (eg, gentamicin) is a possible alternative to aerosolization. Corticosteroids may help alleviate clinical signs but should be used concurrently with an antibacterial agent; they are contraindicated in severely ill, coughing dogs.

Prevention: Dogs should be immunized with modified-live virus vaccines against distemper, parainfluenza, and CAV2, which also provides protection against CAV-1. Commercial products frequently combine these agents and may include modified-live parvovirus and leptospiral antigens. An initial vaccination should be given at 6–8 wk and repeated twice at 3- to 4-wk intervals until the dog is 14–16 wk old. Revaccination should be performed annually. When the risk of *B bronchiseptica* infection is significant, a live, avirulent, intranasal vaccine or parenteral products containing subunit bacterial extracts should be used. A combination of an avirulent *B bronchiseptica* and a modified-live parainfluenza vaccine is available for intranasal use. One inoculation is administered to puppies >3 wk old.

URINARY SYSTEM INTRODUCTION

Primary functions of the urinary system include: 1) excretion of waste products of metabolism; 2) maintenance of a constant extracellular environment through conservation and excretion of water and electrolytes; 3) production of the hormone erythropoietin, which regulates hematopoiesis; 4) production of the enzyme renin, which regulates blood pressure and sodium reabsorption; and 5) metabolism of vitamin **D** to its active form (1,25-dihydroxycholecalciferol).

Many abnormalities of the urinary system can be diagnosed from the signalment, history and physical examination findings, serum chemistry profile, urinalysis, and aerobic bacterial urine culture. The history should include information regarding changes in water consumption, frequency of urination, volume of urine produced, appearance of urine, and behavior of the animal. It is also important to obtain information about historical and current drug administration, appetite, diet, changes in body weight, and previous illnesses or injuries.

The physical examination should include palpation of the bladder and examination of external genitalia. In dogs, rectal examination should be performed to evaluate the urethra in both sexes and the prostate in male dogs. Rectal examination in cats may not be feasible because of their small size; however, the kidneys are generally easier to palpate in cats than in dogs. A full neurologic examination should be performed on all animals with micturition disorders. Additional diagnostic tests, such as CBC, blood gas analysis for acid-base status, blood pressure, urine protein:creatinine ratio, iothexol clearance test, survey abdominal radiography, abdominal ultrasonography, contrast studies of the upper and lower urinary tract, cystoscopic examination of the urinary bladder, and renal biopsy may also provide valuable information.

Urinalysis: One of the most important diagnostic tests for evaluation of urinary tract disorders is a urinalysis. (*See also* p 1615.) Urine may be collected by one of four methods: spontaneous micturition, manual compression of the urinary bladder, catheterization, and cystocentesis. Each method has advantages and disadvantages (*see* TABLE 1). A urinalysis should include method of collection, urine specific gravity, color, turbidity, pH, glucose, ketones, bilirubin icotest, occult blood, protein, and leukocytes (urine dipstick leukocyte tests are unreliable in cats). Urine specific gravity should be obtained using a refractometer. Microscopic examination of urine sediment should include RBCs, WBCs, epithelial cells, renal casts, bacteria, yeast, parasitic ova, fat, sperm, and crystals. Delay in analyzing urine samples can result in artifacts (eg, changes in urine pH, formation of crystals, etc), so it is important to note the time when the sample was collected and the time when it was analyzed. If a sample will not be analyzed immediately, it should be refrigerated.

Protein in urine should be evaluated in light of the specific gravity. Protein in a concentrated urine sample may not be significant, whereas the same amount in a dilute sample may be significant. Urine dipsticks provide a semiquantitative assessment of protein and can be influenced by urine pH. Therefore, they should be used only as a screening test for protein, not as a definitive diagnosis of proteinuria. A urine protein:creatinine ratio from a single urine sample or from a 24-hr urine sample is required to quantitate the amount of protein in urine. In dogs, the following International Renal Interest Society (IRIS) guidelines should be used for interpretation of urine protein:creatinine ratios. In dogs, <0.2 = nonproteinuric, 0.2 – 0.5 = borderline proteinuric, and >0.5 = proteinuric; in cats, <0.2 = nonproteinuric, 0.2 – 0.4 = borderline proteinuric, and >0.4 = proteinuric. Urine

TABLE 1 ADVANTAGES AND DISADVANTAGES OF URINE COLLECTION METHODS

Method of Collection	Advantages	Disadvantages
Spontaneous micturition	No risk (eg, trauma, bacterial infection) to animal. Avoids iatrogenic hematuria.	May contain debris (eg, bacteria, exudate) from lower urinary and genital tract. If bacterial growth appears on urine culture, must differentiate between urethral contamination and urinary tract infection. Quantitative urine culture required.
Manual compression of urinary bladder	Provides method to obtain urine sample when voluntary micturition has not occurred.	May induce trauma to urinary tract, resulting in hematuria. May be stressful for animal, especially if bladder is painful. If bacterial growth appears on urine culture, must differentiate between urethral contamination and urinary tract infection. Quantitative urine culture required.
Catheterization	Provides method to obtain urine sample when other methods of collection have failed.	Potential for trauma to urinary tract, especially urethra. More invasive than other methods; sedation may be required. Risk of introducing bladder infection. If bacterial growth appears on urine culture, must differentiate between urethral contamination and urinary tract infection. Quantitative urine culture required. Least desirable method of urine collection.
Cystocentesis	Preferred method of collection for urine culture. Avoids contamination of sample from lower urinary tract.	Potential risk of trauma if performed incorrectly or animal moves during procedure. Potential for iatrogenic hematuria. More invasive than spontaneous micturition. Potential for bacterial contamination of sample if needle penetrates colon during procedure.

protein:creatinine ratios must be interpreted in the context of other information from the urinalysis. Inflammation and hematuria can falsely increase urine protein:creatinine ratios, although hematuria generally has minimal effects.

Bacterial Culture of Urine: A urinalysis is unreliable to exclude a urinary tract infection (UTI). Not all UTIs are associated with an inflammatory response. In addition, >10,000 bacterial rods/mL and >100,000 bacterial cocci/mL of urine are required to consistently find bacteria in a urine sample using light microscopy. Approximately

25%–30% of all dogs with UTI have urine bacterial counts below these figures at the time of specimen collection, so urine culture is important to exclude a UTI.

Urine samples for bacterial culture may be obtained by the same methods used to obtain samples for urinalysis; however, the preferred method is cystocentesis. Urine obtained by cystocentesis should be sterile. If urine samples are collected by methods other than cystocentesis, a quantitative urine culture should be requested. If the sample is collected by spontaneous micturition or manual compression, significant numbers of bacteria are present if $\geq 100,000$ colony

forming units (CFU)/mL of urine in dogs or $\geq 10,000$ CFU/mL of urine in cats are detected. Samples with $>10,000$ – $90,000$ CFU/mL in dogs and $>1,000$ – $10,000$ CFU/mL in cats are suspicious for a UTI. If the sample is collected by catheterization, $\geq 10,000$ CFU/mL in dogs and $\geq 1,000$ CFU/mL in cats is significant, whereas samples containing $1,000$ – $10,000$ CFU/mL in dogs and 100 – $1,000$ CFU/mL in cats are suspicious for a UTI.

Serum Chemistry Profile: Evaluation of serum chemistries, including BUN, creatinine, calcium, phosphorus, bicarbonate, and serum electrolytes, is useful in many urinary tract disorders and can provide a crude indication of glomerular filtration rate (GFR). Although increases in BUN and creatinine are supportive of renal dysfunction, these tests are influenced by nonrenal factors as well. For example, dehydration can cause increases in BUN and serum creatinine not associated with renal failure. BUN can also be influenced by diet and GI bleeding and is considered inferior to creatinine to evaluate GFR. Serum creatinine levels can be falsely decreased in animals with severe muscle wasting and falsely increased in animals with severe muscle damage. Although BUN and serum creatinine increase as GFR decreases, this relationship is not linear. Large changes in GFR early in renal disease cause only small increases in BUN and serum creatinine, whereas small changes in GFR in advanced renal disease may be associated with large changes in BUN and serum creatinine.

Additional Diagnostic Tests: More sensitive methods to detect renal dysfunction include plasma clearance tests (eg, inulin clearance), radionuclide techniques, endogenous creatinine clearance, and exogenous creatinine clearance. However, these tests are impractical to perform routinely in clinical practice. The iothexol

clearance test is a recently developed alternative to detect renal dysfunction. It entails recording an accurate body weight, administering a precise amount of iothexol IV, and accurately timing the collection of blood samples as directed after administration. This test does not require timed collection of urine samples or special equipment. Plasma clearance of exogenous creatinine has also recently been validated for use in dogs.

Depending on the cause of the urinary tract disorder, radiographic procedures, sonographic examination, and cystoscopic examination of the bladder may provide additional valuable information. The kidneys have a limited range of responses to disease; therefore, renal biopsies are rarely useful when evaluating renal dysfunction. An exception to this is in animals with significant proteinuria.

Blood gas analysis or serum bicarbonate levels provide useful information on acid-base status, especially in animals with renal dysfunction. Metabolic acidosis is a common problem in chronic renal failure and can result in protein catabolism.

PRINCIPLES OF THERAPY

Diseases of the urinary system can result from a variety of pathologic processes, and appropriate therapy (as discussed in the following chapters) depends on the location, severity, and cause of the problem. *See also* SYSTEMIC PHARMACOTHERAPEUTICS OF THE URINARY SYSTEM, p 2617. If the condition is not life threatening, appropriate diagnostic samples should be collected before initiating therapy. It is important to remember that some diagnostic tests and treatments have the potential to cause significant harm. If the specific cause cannot be determined, nonspecific and supportive therapy (eg, monitoring fluids, treating acidosis) should be instituted.

CONGENITAL AND INHERITED ANOMALIES OF THE URINARY SYSTEM

Congenital and inherited anomalies of the urinary system comprise a group of anatomic defects that, although uncommon, may have subclinical to serious functional consequences.

RENAL ANOMALIES

Renal Dysplasia and Hypoplasia:

These defects are most common in dogs and have been reported in many breeds,

including Alaskan Malamutes, Bedlington Terriers, Chow Chows, Cocker Spaniels, Doberman Pinschers, Keeshonden, Lhasa Apsos, Miniature Schnauzers, Norwegian Elkhounds, Samoyeds, Shih Tzus, Soft-coated Wheaten Terriers, and Standard Poodles. Renal dysplasia is rare in cats, lambs, and horses. In pigs, renal dysplasia may be idiopathic or associated with nutritional avitaminosis A.

Renal dysplasia may be unilateral or bilateral. Animals affected bilaterally generally die in the early neonatal period, whereas animals affected unilaterally typically develop hypertrophy of the contralateral kidney. The kidneys are usually small, firm, and pale; they may have a uniformly diminished renal cortex. Histologic examination reveals immature glomeruli, primitive tubules, and secondary inflammatory lesions, especially interstitial fibrous connective tissue.

Polydipsia and polyuria usually precede signs of uremia. Dwarfing may be noticed if the onset of renal failure occurs within the first few months of life. Urinalysis, hemogram, and blood chemistry changes are the same as in other chronic, progressive renal diseases. Uremia is usually identified between 6 mo and 2 yr of age. The diagnosis is suspected based on the breed and age of disease onset and is confirmed by renal biopsy. Treatment is aimed at managing the associated chronic renal failure.

Renal Agenesis: Renal agenesis, the complete absence of one or both kidneys, is always accompanied by ureteral aplasia and may be associated with aplastic reproductive tissues on the same side. The condition is typically an incidental finding so long as the other kidney functions normally; frequently, the contralateral kidney undergoes compensatory hypertrophy. Renal agenesis is believed to have familial predisposition in Beagles, Shetland Sheepdogs, and Doberman Pinschers. Unilateral renal agenesis is the most common congenital kidney condition in pigs; it is less common in sheep, cattle, and goats. Bilateral agenesis results in early perinatal death.

Polycystic Kidneys: Multiple cysts form within the renal parenchyma, and such kidneys are usually grossly enlarged on palpation. This condition may be associated with hepatic biliary cysts in both dogs and cats. Polycystic kidneys may cause no clinical signs or lead to progressive renal failure. This condition is familial in Beagles, Bull Terriers, Cairn Terriers, and West Highland White Terriers. Polycystic kidneys

are an autosomal dominant inherited trait in Persian cats and domestic long-haired cats. Polycystic kidneys are also hereditary in pigs and may alternatively be associated with avitaminosis A. Polycystic kidneys are rare in cattle and horses and very rare in sheep. Diagnosis is based on physical and radiographic findings, ultrasonic examination, or exploratory laparotomy. Pyelonephritis may be seen concurrently and precipitate renal insufficiency.

Simple Renal Cysts: These solitary, unilocular cysts generally do not communicate with the renal collecting system; the rest of the kidney is normal. The origin of these cysts is uncertain. They are usually an incidental finding in all domestic species.

Perirenal Pseudocysts: Perirenal pseudocysts are accumulations of fluid that develop external to the renal parenchyma. They have been identified in cats. Their origin is unknown. The accumulated fluid may be located between the renal parenchyma and the renal capsule or between the renal capsule and a thin-walled fibrous sac attached to the capsule. They are termed pseudocysts rather than cysts because they are not lined by epithelium. Because only a limited number have been examined histologically, it is unknown whether all perirenal fluid-filled structures are pseudocysts. The fluid contained within these structures is not urine or lymph but is described as a transudate. Clinical signs are characterized by progressive abdominal enlargement. Abdominal palpation reveals a large, firm, nonpainful mass located in the area of the kidneys. Renal function tests and urinalysis are typically normal; however, a mild azotemia may occur. Diagnosis is made by excretory urography or ultrasonography. Treatment involves exploratory surgery to confirm the diagnosis, drainage of the pseudocyst fluid, and resection of as much of the pseudocyst wall as possible. The prognosis appears to be good; however, only a limited number of cases have been evaluated.

Miscellaneous Renal Anomalies: Double or multiple renal arteries are seen in ~5% of dogs. Other congenital defects include renal malpositioning, renal fusion, and nephroblastoma. Nephroblastoma is an embryonal tumor and is rare in domestic animals except pigs. It may cause no problems but may be very large and cause abdominal distention.

URETERAL ANOMALIES

Ectopic Ureter: This defect is most commonly reported in 3- to 6-mo-old dogs, with female dogs affected 8 times more frequently than male dogs. In dogs, ectopic ureter has a reported incidence of 0.016%–0.045%. In horses, ectopic ureter is the most common congenital anomaly affecting the urinary tract; as in dogs, it is significantly more common in fillies than in colts. Ectopic ureters are infrequently identified as a clinical problem in cattle, sheep, or pigs. Other anomalies frequently associated with ectopic ureter include hydroureter, hydronephrosis, renal hypoplasia, bladder hypoplasia, and urethral sphincter incompetence. Continual dripping of urine is the classic sign, although animals with unilateral ectopic ureter may void normally; the inability to void normally suggests bilateral ectopic ureters. A low-grade vaginitis or vulvitis may also be present due to urine scalding. Involved ureters may open into the urethra, the uterus, or the vagina. Unilateral ectopic ureter is seen with equal frequency on right and left sides, and involvement is bilateral in ~25% of cases. Ectopic ureters generally result from disruption of development of the mesonephric and metanephric duct systems. A genetic component is suspected on the basis of identifying high-risk breeds (West Highland White Terriers, Fox Terriers, and Miniature and Toy Poodles) and a familial occurrence in Siberian Huskies and Labrador Retrievers. Diagnosis is confirmed by IV urography that traces the course of the ureter.

Successful surgical treatments usually involve transplantation of affected ureters into the bladder, or ureteronephrectomy. A recent review of surgically repaired ectopic ureters in female dogs indicated that factors including left- or right-sided ectopic ureter, unilateral or bilateral ectopic ureter, presence of hydroureter, or presence of urinary tract infections were not significant to influencing postoperative incontinence. Another study showed that female dogs with ectopic ureters treated by cystoscopic-guided laser ablation had a 47% postoperative success rate based on their maintaining urinary continence. Additional medical management further improved the urinary continence rate to 77%. Indications for ureteronephrectomy may include severe ipsilateral renal disease such as hypoplasia, hydronephrosis, or pyelonephritis in the presence of a normally functioning contralateral kidney. Important postoperative complications are persistent incontinence, hydronephrosis, and dysuria.

Incontinence occurs most often in cases of bilateral ectopic ureters and may be due to abnormal development of the bladder neck and urethra. An adrenergic agent such as phenylpropanolamine (0.5–1.5 mg/kg, PO, bid-tid) may help minimize the incontinence.

Miscellaneous Ureteral Anomalies:

Less frequently recognized ureteral anomalies include aplasia, duplication, and ureterocele. Ureteroceles are characterized by dilation of the submucosal ureter segment within the bladder. Diagnosis is by excretory urography. Appropriate therapy is ureteronephrectomy if the lesion is unilateral with secondary hydronephrosis and hydroureter. If the proximal ureter and kidney are normal, excision or incision of the ureterocele, in addition to ligation of any ectopic distal channel, has been successful.

BLADDER ANOMALIES

Urachal Remnants: Congenital anomalies resulting from incomplete urachal closure include patent urachus, urachal diverticulum, umbilical urachal sinus, and intra-abdominal urachal cyst. These conditions may be seen in any domestic species but are most frequently a clinical problem in cats, dogs, and horses. Clinical signs and appropriate therapy depend on the type of anomaly. Patent urachus is typically associated with continuous urinary incontinence, urine scalding of the ventral abdomen, and development of bacterial urinary tract infections. Urachal diverticula also predispose to urinary tract infection by serving as a nidus for bacteria. Definitive diagnosis of both disorders is by positive contrast cystography. Treatment consists of surgical resection and 2–4 wk of appropriate antibiotic therapy when indicated. Surgical resection is the standard treatment for umbilical urachal sinuses and intra-abdominal urachal cysts.

Miscellaneous Bladder Anomalies:

Bladder duplication, dysplasia, hypoplasia, agenesis, and exstrophy (congenital eversion) have been reported and are often associated with other urinary tract defects. Diagnosis is by physical examination, observation of micturition, and contrast radiography. Clinical signs and therapy depend on the type of anomaly.

URETHRAL ANOMALIES

Congenital or hereditary urethral anomalies are uncommon in all domestic species; they include urethral agenesis, imperforate

urethra, hypospadias, epispadias in combination with bladder exstrophy, urethral duplication, urethral diverticula, urethrorectal fistula, and urethral stenosis.

Hypospadias: This developmental defect results from failure of the urethral grooves to fuse during phallus elongation. The urethral opening is ventral and caudal to the tip of the penis and is classified on the basis of anatomic localization as glandular, penile, scrotal, perineal, or anal. The penis or scrotum may be underdeveloped as well. This uncommon anomaly is most frequently seen in male dogs; the highest prevalence is seen in Boston Terriers, suggesting a genetic basis. The condition is also rarely seen in bulls. Clinical signs depend on the site of the urethral meatus and include urine scalding and complications of increased susceptibility to urinary tract infection. Although surgical correction also depends on the site

of the urethral meatus, a modification of the prescrotal urethrostomy is generally useful.

Urethrorectal and Rectovaginal

Fistulas: These congenital anomalies predominantly affect dogs, cats, and horses. The anomalies are more common in males than females; males are more likely to develop urethrorectal fistulas, whereas in females the rectovaginal fistulas predominate. In dogs, English Bulldogs seem to have a breed predisposition, possibly as a congenital defect due to abnormal separation of the embryonal cloaca into the urethra and rectum. Clinical signs include hematuria and dysuria secondary to urinary tract infection. Simultaneous passage of urine from the anus and urethra during micturition may be noted. Appropriate therapy consists of surgical correction and concurrent management of urinary tract infection.

INFECTIOUS DISEASES OF THE URINARY SYSTEM IN LARGE ANIMALS

BOVINE CYSTITIS AND PYELONEPHRITIS

(Contagious bovine pyelonephritis)

Bovine cystitis is an inflammation of the urinary bladder of cattle that may ascend the ureters to cause infection of the kidneys (pyelonephritis). A similar condition is seen in sheep. The condition is sporadic and worldwide in distribution. Cystitis and pyelonephritis are most often seen after parturition (in one study, the average days to onset after parturition was 83), with multiparous cows being at highest risk. In locations where the disease has been studied, the prevalence is low (<1%–2%). Cystitis and pyelonephritis are rare in male cattle.

Etiology and Pathogenesis: Formerly, the most common causative agents were the *Corynebacterium renale* group of bacteria, including *C. renale*, *C. cystitidis*, and *C. pilosum*, as well as *Escherichia coli*; however, *E. coli* and *Trueperella* (formerly *Arcanobacterium* or *Corynebacterium*) *pyogenes* are now the bacteria most frequently isolated from cows with pyelonephritis. Other opportunistic and environmental bacteria may be involved, including staphylococci and streptococci.

The most common causative bacteria are ubiquitous in the environment and are common inhabitants of the vagina and prepuce. Pyelonephritis develops from an ascending infection from the bladder. Cystitis may be present without involving the ureters or ascending to the kidney until some event occurs that compromises the defense mechanism of the ureteral mucosa. The organisms attack or colonize the mucosal lining of the bladder and ureters usually after some traumatic insult (such as parturition or abnormal deformity of the vaginal tract). The stresses of parturition, peak lactation, and a high-protein diet (which increases the pH of the urine and is therefore conducive to colonization of the urinary tract by *Corynebacterium* spp) are all contributing factors. Routine catheterization of the bladder with nonsterile catheters may facilitate transmission of *Corynebacterium* spp from cow to cow. The decrease in the frequency of urinary catheterization has been associated with a decreased prevalence of *Corynebacterium* spp as a cause of pyelonephritis.

Clinical Findings and Lesions: The first sign observed may be the passage of blood-stained urine in an otherwise healthy

cow. As the infection proceeds up the ureters, causing inflammation and subsequent involvement of the kidney, the animal exhibits discomfort manifest by frequent attempts to urinate, anorexia, a slight fever, loss of production, colic with restlessness, tail switching, polyuria, hematuria, or pyuria. In chronic cases, the animal may show colic, diarrhea, polyuria, polydipsia, stranguria, and anemia. As the disease progresses, the bladder becomes thickened and inflamed. The ureters become thickened and dilated with a purulent exudate. The involved kidneys develop multiple small abscesses on the surface that may extend into the cortex and medulla.

Diagnosis: Diagnosis is based on clinical signs; hematuria; a history of recent parturition; palpation of the left kidney for enlargement, loss of lobulation, and pain; ultrasonographic inspection of the kidneys, ureters, and bladder; endoscopic inspection of the bladder for detection of cystitis; microscopic examination of the urine for WBCs and bacteria; dipstick screening for proteinuria and hematuria; and quantitative urine culture to identify the organism. The right kidney cannot be palpated per rectum, except for the caudal pole in Jersey cows and heifers. In early acute cases of pyelonephritis, enlarged ureters and involvement of the kidney may not be detectable on palpation per rectum. Typically, only one kidney is affected.

Treatment: Early diagnosis and prompt, sustained treatment are needed for a successful recovery. A catheterized urine sample should be taken for culture and antimicrobial susceptibility testing. The treatment of choice for pyelonephritis due to *Corynebacterium* spp is penicillin (22,000 IU/kg, IM, bid) or trimethoprim-sulfadoxine (16 mg combined/kg, IM, bid) for ≥ 3 wk. The dosage, frequency, and length of administration for both of these drugs is extra-label, and adequate precautions must be taken to prevent antibiotic residues from entering the human food supply. *E coli* infections require a broad-spectrum antimicrobial. Ceftiofur (1.1–2.2 mg/kg/day, IM or SC) or gentamicin (2.2 mg/kg, IM, bid) for ≥ 3 wk have been used successfully in some cases. Because of the extremely long tissue-depletion time, the aminoglycosides may not be indicated in food-producing animals. Manipulation of urine pH may theoretically be of value because *E coli* grow best in acidic urine (pH <7), whereas *Corynebacterium* spp grow best in alkaline urine (pH >7). Nonazotemic animals with

pyelonephritis confined to one kidney may benefit from unilateral nephrectomy.

Even though the organisms are ubiquitous in the environment, affected animals should be isolated from the herd to restrict buildup of organisms. Because of suspicion that bulls may act as mechanical vectors of *Corynebacterium* spp, artificial insemination in herds with multiple animals affected may be considered.

PORCINE CYSTITIS–PYELONEPHRITIS COMPLEX

Porcine cystitis-pyelonephritis complex, a leading cause of mortality in sows, has been reported throughout the world. Increased incidence appears to be correlated with changes in management, particularly the adoption of confinement housing for gestating sows. Distinguishing features of endemic cystitis and pyelonephritis within a herd include lack of a temporal relationship between the vulvar discharge and the estrous cycle, minimal effect on herd fertility, low morbidity, high mortality, and an increased frequency in advanced-parity (6+) sows.

Etiology and Pathogenesis: A wide variety of bacteria has been isolated from cases of porcine cystitis and pyelonephritis, including *Escherichia coli*, *Arcanobacterium pyogenes*, and *Streptococcus* and *Staphylococcus* spp. These endogenous and opportunistic organisms typically inhabit the lower urinary tract and are often referred to as being responsible for nonspecific urinary tract infections. *Actinobaculum suis*, a specific urinary pathogen, is an important cause of ascending infection in swine. Formerly classified in the genera *Eubacterium* and *Actinomyces*, *A suis* is a gram-positive, rod-shaped bacterium that grows well under anaerobic conditions and is a commensal organism of the porcine urogenital tract. *A suis* is finbriated, and the short, wide urethra of the sow enhances accessibility to the bladder.

Once within the bladder lumen, the alkalinity of the environment increases due to the cleavage of urea into ammonia via the urease enzyme. The increased pH enhances bacterial proliferation and inflames the mucosal surface. The alkaline environment also inhibits the growth of competitive microflora and promotes precipitation of urinary salts and crystals, particularly struvite. Such precipitates not only further increase inflammatory changes in the bladder mucosa but also provide a nidus for bacterial growth and protection from antibiotics and host defense mechanisms.

Although the primary means of accessibility to the kidneys is not yet completely understood, it is hypothesized that damage to the ureteric valves secondary to bacterial products (possibly originating from *E coli*) may predispose affected animals to pyelonephritis.

Epidemiology: Problems frequently encountered in confinement facilities that hasten the development of porcine cystitis are the reduced availability of water, increased fecal contamination of the perineal area, excessive weight gain, and leg injuries, all of which result in a reduced frequency of urination and enhanced bacterial survival in the urogenital tract. The problem may not be as prevalent in outdoor, loose housed sows; however, data are lacking. *A suis* has been isolated from the preputial cavity of boars at slaughter, the vaginal tract of neonatal piglets sampled immediately after parturition, and the vaginal tract of sows sampled throughout all stages of production. It may also be isolated from voided urine, contaminated parturition sleeves of farrowing attendants, pen floors of farrowing and nursery rooms, and the boots of stockpersons working in the breeding area. The organism is ubiquitous, and the vaginal tract can become colonized anytime during the life of the pig.

Clinical Findings: Clinical signs vary according to the severity and phase of the disease. In acute and severe cases, affected pigs may be found dead, probably from acute renal failure. Symptomatic animals are usually afebrile and may show anorexia, hematuria, and pyuria. The urine is typically reddish brown with a strong odor of ammonia. Urinary pH may increase from normal values of 5.5–7.5 up to 8–9. Animals that survive the initial infection frequently experience weight loss and reduced productivity secondary to end-stage renal disease, resulting in premature removal from the breeding herd. Inflammatory reaction on the mucosal surface of the bladder may be catarrhal, hemorrhagic, purulent, or necrotic, and the bladder wall may be thickened. Struvites can also be found in the lumen. The ureters, often filled with exudate, may increase to as much as 2.5 cm in diameter. Unilateral or bilateral pyelonephritis or pyelitis is the primary lesion in the kidneys. The pelvic region of the kidney, frequently distended with blood, pus, and foul-smelling urine, often shows irregular ulceration and necrosis of the papillae. In longstanding cases of pyelonephritis, fibrosis ultimately replaces inflammation.

Diagnosis: Cystitis and pyelonephritis in live animals can best be presumptively diagnosed when frequent micturition of bloodstained and cloudy urine can be observed. Examination of the urine sediments may reveal the presence of inflammatory cells, RBCs, granular renal casts, bacteria, and crystals. Because of the striking gross lesions, confirmation of the diagnosis is usually not difficult. To properly isolate the causative organism, care must be taken during sample collection to minimize exposure to oxygen. In the field, the bladder should remain unopened, and the neck of the bladder should be sealed with umbilical tape. Similar care should be taken with renal tissue. Lesions of pyelonephritis can be demonstrated by examination of one kidney; the other should remain unopened with the ureter sealed as previously described. Cultures should be grown on colistin nalidixic acid agar at 37°C (98.6°F) under anaerobic conditions for 5–7 days. If the culture is to be done at a distant location, swabs can be placed into Kary Blair anaerobic transport media for shipment. A PCR test for *A suis* has been described and appeared to have better sensitivity than direct culture. Data indicate detection of 1–2 CFU/mL of urine, and the pathogen can be successfully detected in samples of sow urine and boar preputial cavity.

Treatment and Prevention: Treatment of urinary tract infections may be successful if the correct antibiotic is administered early in the disease course. Penicillin and ampicillin are often the drugs of choice because of their effectiveness in alkaline conditions and their propensity for excretion through the urinary tract. Dosages of 2.2 mg/kg are typically administered IM for 3 days. Water-soluble ampicillin can be administered at 2.3 mg/kg for 5 days, although bioavailability is questionable and cost may become an issue. Acidification of the urine through oral administration of feed-grade citric acid has been reported. Results showed a reduced incidence of clinical urinary tract disease, as well as highly significant ($P < .0001$) differences in urinary pH and bacterial concentration/mL of urine in medicated versus nonmedicated groups. A level of 70 mg of citric acid was administered daily for 14 days with no palatability problems.

Maintaining excellent hygiene during breeding and parturition, as well as throughout the gestation period, is critical to prevent urinary tract disease. Facilities must be properly designed to reduce the spread of pathogens within the breeding

herd and to allow for efficient removal of feces from the environment. Free-choice water should be available at all times, because restricting water availability through use of intermittent delivery systems or poor husbandry results in an increase in abnormal urine parameters in gestating sows, including decreased urine output, increased specific gravity (>1.026), and increased creatinine concentration. Finally, because a higher degree of urinary tract disease can be seen in older sows, proper culling procedures are important to ensure that an optimal parity distribution is maintained within breeding herds.

SWINE KIDNEY WORM INFECTION

Etiology: *Stephanurus dentatus* are stout-bodied worms (2–4.5 cm long) found encysted in pairs along the ureters in the perirenal fat and in the kidney. The kidney worm is found worldwide, particularly in tropical and subtropical areas. It is primarily a parasite of swine raised outdoors in the southeastern and south central USA. The eggs hatch shortly after being passed in the urine and reach the infective stage in 3–5 days. The larvae are susceptible to temperature extremes, desiccation, and sunlight. Infection is by skin penetration or ingestion of the infective larvae (earthworms may serve as paratenic hosts). The larvae enter the liver, where they migrate extensively for 3–9 mo. Larvae then penetrate the capsule and migrate through the peritoneal cavity to the perirenal area, where they find their way into the ureters, kidney, and perirenal fat. Occasionally,

some larvae errantly migrate to other tissues and organs or to developing fetuses. Infections usually become patent in 9–16 mo but may be found as early as 6 mo.

Clinical Findings and Diagnosis: When present in large numbers, kidney worms may adversely affect growth. The principal economic loss results from condemnation of organs and tissues affected by migrating larvae. The most severe lesions are usually in the liver, which shows cirrhosis, scar formation, extensive thrombosis of the portal vessels, and a variable amount of necrosis. Kidney and lung damage are also possible.

When worms are in the kidney or in cysts that open into the ureter, eggs may be recovered in the urine. Prepatent infections are difficult to diagnose, and a definitive diagnosis depends on demonstration of the worms or lesions at necropsy.

Control: Good control practices are indicated in areas where the worm is found. Because of the long prepatent period, control may be achieved with a “gilts only” breeding program, which prevents patent infection from developing. Older boars are replaced with young boars from clean herds, and only gilts are bred and then sold after weaning. Eradication is possible within 2 yr. More commonly, anthelmintics and sanitation (rearing on concrete or in confinement) are used to control kidney worm.

Ivermectin (in-feed for 7 days at 1.8 g/ton), fenbendazole (in-feed for 3–12 days at 9 mg/kg/day), or levamisole (in-feed at 0.36 g/ton) are effective against *Stephanurus* sp. Doramectin (single injection at 300 mcg/kg) is also approved for use against this worm.

NONINFECTIOUS DISEASES OF THE URINARY SYSTEM IN LARGE ANIMALS

UROLITHIASIS

For a more general introduction to urolithiasis, see p 1525.

Urolithiasis in Ruminants

Uroliths in cattle, sheep, and goats are common. Although uroliths can be found anywhere within the urinary tract, urethroliths are responsible for most clinical problems. Obstruction induced by urethroliths causes urine retention and

leads to bladder distention, abdominal pain, and eventual urethral perforation or bladder rupture, with death from uremia or septicemia. It is an important disease of feeder animals but is also seen in mature breeding animals. Urolithiasis is seen most often during winter in steers and wethers on full feed, or on range during severe weather conditions with limited water intake, especially when the water has a high mineral content. Obstructive uroliths are common in male goats, regardless of feed, season, or other risk factors. Urolithiasis

has no specific geographic distribution, and the different urolith types reflect the mineral distribution of the feed. Uroliths occur in either sex, but obstructive urolithiasis develops primarily in males because of anatomic differences.

Etiology and Pathogenesis: Ruminant urolithiasis is considered primarily a nutritional disease. The prevalence of urolithiasis in the USA is highest in calves, lambs, and kids castrated at an early age and fed high-grain diets with roughly a 1:1 calcium:phosphorus ratio or a diet high in magnesium. Ruminants fed high-grain diets with a low calcium:phosphorus ratio are at increased risk of developing struvite uroliths, whereas ruminants grazing on silica-rich soil are predisposed to form silica uroliths. Diets high in calcium (eg, subterranean clover) may result in calcium carbonate uroliths, while plants such as halogeton or tops from the common sugar beet may be a factor in calcium oxalate formation. The mineral composition of water, in concert with dietary mineral imbalances, probably contributes more to initiating urolith formation than does the lack of water itself. A definitive diagnosis of urolithiasis in a single animal suggests that all males in the population are at risk of the disease. Struvite calculi have the appearance of sand, whereas calcium carbonate calculi and calcium oxalate are distinct, round stones.

The distal aspect of the sigmoid flexure of cattle and the sigmoid flexure and urethral process of sheep and goats are the most common sites for uroliths to lodge. Irritation at the site of lodging causes inflammation and swelling that contributes to urethral occlusion. Castration of young males also predisposes to urolith-induced urethral obstruction by removing hormonal influences necessary for mature development of the penis and urethra.

Clinical Findings: Clinical signs may be associated with partial or complete urethral occlusion. Animals with partial obstruction dribble blood-tinged urine after prolonged, painful (stranguria) attempts at urination; before complete occlusion occurs, urine may dry on the preputial hairs and leave detectable mineral deposits. Animals with complete urethral obstruction exhibit tenesmus, tail twitching, weight shifting, and signs consistent with colic. Inappetence, bloat, depression, and rectal prolapse also may be seen. Affected steers may elevate the tail and show urethral pulsations just ventral to the rectum. Goats may vocalize.

Common sequelae of complete urethral obstruction include urethral perforation, hydronephrosis, or urinary bladder rupture. Bladder rupture often results in death from uremia. The disease course may be 5–7 days. Although urethral perforation may also cause uremia and death, it is not uncommon for the ventral abdominal skin to necrose and slough, allowing a pseudo-urethra to develop.

Diagnosis: Diagnosis based on the history, clinical signs, and physical examination is usually straightforward. Hypersensitivity in the region of the sigmoid flexure may be evident. Palpation may identify abnormal pulsations of the urethra and tissue swelling associated with the obstruction. Rectal palpation may reveal an enlarged, distended bladder, or the bladder may be nonpalpable, consistent with bladder rupture. Examination of the urethral process in sheep and goats may reveal the occluding urolith. In small ruminants, the distended bladder can be felt by abdominal palpation and visualized on ultrasound examination. Calcium carbonate and calcium oxalate calculi can be seen on radiographs of the urethra in small ruminants; struvite calculi are not seen on radiographs. If early clinical signs of obstructive uropathy are missed, the animal may show only inappetence, depression, subcutaneous swelling along the penis, or uroperitoneum; abdominal distention due to uroperitoneum must be differentiated from ruminal tympany, peritonitis, peritoneal tumors, uterine hydrops, and GI tract obstructions. Ballottement allows detection of the fluid, and when viewing the animal from behind, the abdomen appears symmetrically enlarged and pear-shaped. Ultrasound examination of the abdomen reveals a large amount of hypochoic fluid.

Confirmation of ruptured bladder is obtained by examining fluid collected by abdominocentesis and finding that the amount of creatinine in peritoneal fluid is two times or more than in plasma. Subcutaneous swellings along the prepuce and ventral abdomen due to a perforated urethra must be differentiated from traumatic injury, subcutaneous abscesses, and umbilical or ventral hernias. In breeding animals, preputial lacerations with prolapse and sheath infection, and hematoma of the penis must also be differentiated. In animals with clinical signs of acute colic, other causes of abdominal pain must be eliminated; these diseases include indigestion, stasis or obstruction of the GI tract, primary enteritis, abomasal ulcers, and coccidiosis.

Treatment and Control: Treatment of obstructive urolithiasis generally involves establishing a patent urethra and correcting fluid and electrolyte imbalances. In many instances, surgical management of the obstruction is all that is necessary; however, severely uremic and depressed animals require rehydration and correction of acid-base and electrolyte abnormalities, especially hyperkalemia or hyperanionemia. If a rupture of the urinary tract has occurred, hyponatremia, hypochloremia, hyperphosphatemia, and metabolic alkalosis with variable potassium concentrations are found. Treatment with IV normal saline is indicated. The volume of fluid administered should be calculated to correct clinical dehydration. Once the animal is rehydrated and any rupture repaired, fluid therapy may be continued to encourage diuresis.

Animals with an intact urethra and bladder that have early clinical signs of obstructive urethral disease may benefit from conservative therapy using antispasmodics and tranquilizers. This is believed to relax the retractor penis muscles with straightening of the sigmoid flexure. However, conservative therapy is only rarely beneficial in small ruminants and is warranted only in cases of acute or partial obstruction without evidence of urethral or bladder damage; it should not be used in complicated or advanced cases. Uroliths trapped within the urethral process of sheep and goats may be removed by gentle manipulation or by amputation of the urethral process. Proper restraint, tranquilization, and a regional anesthetic are necessary. The techniques vary, but the typical procedure requires exteriorization of the penis. Although amputation may be effective, relief is typically temporary (<2 days) in most animals, because obstruction recurs due to the presence of multiple uroliths.

Perineal urethrostomy has also been recommended as an effective surgical technique in castrated males. Short-term complications associated with perineal urethrostomy may include postoperative hemorrhage, surgical wound dehiscence, and subcutaneous urine accumulation. Urethral stricture is a common long-term complication. Transection of penile attachments to the pelvis may decrease risk of postoperative stricture. In addition, perineal urethrostomy is associated with loss of breeding ability in intact males. In more complicated cases, such as those with urethral perforation, amputation of the penis proximal to the sigmoid flexure or

near the perineal area may be necessary as a salvage procedure. Animals that develop urethral perforation also require drainage of accumulated subcutaneous urine; this is accomplished by lancing the skin overlying the area of accumulated urine. Topical antiseptics and fly repellents may be applied to these ventral lacerations, and parenteral antibiotics are recommended to prevent infection.

Cystotomy followed by dietary management is believed to be a more effective long-term solution to urolithiasis in sheep and goats than is perineal urethrostomy. Cystotomy allows removal of multiple urocystoliths, permits bidirectional urethral flushing, and poses less risk of urethral stricture. Tube cystotomy is generally considered the treatment of choice, allowing time for the calculi to be expelled spontaneously. An intact urethral process, absence of abdominal fluid, and serum potassium concentration <5.2 mEq/L have all been associated with improved survival after tube cystotomy in small ruminants.

If the bladder is ruptured, the ability to urinate must be restored and uremia corrected. In animals with substantial uroperitoneum, the peritoneal cavity should be slowly drained using a teat tube or trocar. Urine removal may also reduce the severity of peritonitis and make the animal more comfortable. Fluid, electrolyte, and acid-base homeostasis normally returns within 24 hr after restoration of a patent urinary system. Persistent uremia indicates the possibility of hydronephrosis or ascending pyelonephritis or both. A urethrostomy should be performed to provide unobstructed passage of urine. Attempts to surgically repair the ruptured bladder have been largely unsuccessful because of the chronic distention before the rupture. The bladder may heal spontaneously after urethrostomy and removal of abdominal fluid; however, these animals are best salvaged within 3–4 mo to avoid further complications. Despite treatment, some animals cannot pass urine effectively, and the uroperitoneum recurs. These animals may be treated by performing tube cystotomy followed by appropriate antibiotic and fluid therapy.

Several measures to prevent the formation of urethral calculi have been recommended. Most important for struvite calculi prevention are to increase urinary chloride excretion, decrease urine pH, and provide a calcium:phosphorus ratio of 2:1 in the complete ration. Intensive concentrate feeding, such as in many finishing programs, frequently leads to urolith

formation and urethral obstruction. Thus, any feeding program that incorporates concentrate feeding must include appropriate calcium supplementation. Adjunct measures to minimize the formation of urethral calculi include adding sodium chloride up to 4% of the total ration. This promotes increased sodium and chloride concentration in the urine, water intake, and urine dilution, which increases the mineral solubility. Ammonium chloride can be used as a urinary acidifying agent (7–10 g/head/day for a 30-kg lamb or kid; 50–80 g/head/day for a 240-kg steer). Complete rations with dietary cation-anion difference (DCAD) are also used to prevent struvite calculi; these rations are high in chloride. Urine acidification antagonizes magnesium-ammonium-phosphate crystal formation and has been shown empirically to be a useful preventive measure. Lower calcium diets should be used if calcium carbonate or calcium oxalate is a concern.

In operations with a significant problem of urolith formation, evaluation of the ration is the most important measure that can be taken to reduce the incidence. Commercial anionic dietary supplements are available for small ruminants.

Urolithiasis in Horses

Urolithiasis is a less common condition in horses than in small ruminants or steers. The disease can affect immature horses but is seen most frequently in adults. There is no breed predilection. Urolithiasis is seen more frequently in males than in females, which has been attributed to anatomic differences between the male and female urethra.

Equine uroliths have a diameter of 0.5–21 cm, weigh as much as 6.5 kg, and are found most often within the bladder. Most equine uroliths are composed of calcium carbonate, in various hydrated forms, with either calcium phosphate or struvite uroliths occasionally noted. Calcium carbonate uroliths have two separate clinical forms. The first form is a concretion of salts and mucoproteins that varies in consistency from friable to firm. These uroliths are usually yellow and oval or irregularly shaped; they frequently have a rough or spiculated surface and are generally soft enough to be fragmented during surgery. The second calcium carbonate form is a firm concretion that is hard and resistant to fragmentation and is typically smooth and white. There appears to be no difference in chemical composition between these forms.

Etiology: The mechanism of urolith formation in horses is unknown, although the alkaline pH and high mineral content of normal equine urine may favor crystal formation and precipitation. Normal equine urine also contains large amounts of mucoproteins, which may serve as a cementing substance to adhere crystals. Consumption of feed and water high in mineral content may increase urinary solute concentrations and thereby promote crystallization and precipitation. Multiple nephroliths may develop in horses with renal papillary necrosis (associated with NSAID administration while dehydrated) and mineralization of the papillae.

Clinical Findings: Clinical signs depend on the urolith location. Most uroliths are located in the bladder and cause dysuria, pollakiuria, and hematuria. Hematuria is most evident after exercise and toward the end of a voided urine stream. Affected horses frequently stretch out to urinate and may maintain this posture for variable periods before and after micturition. Additional signs may include scalding of the perineum in females or of the medial aspect of the hindlimbs in males. Geldings and stallions may protrude the penis flaccidly for prolonged periods while intermittently dribbling urine. Affected horses may occasionally exhibit recurrent bouts of colic or an altered hindlimb gait. Urethral obstruction may also develop as the result of a trapped urolith and is typically accompanied by restlessness, sweating, varying degrees of colic, and frequent attempts to urinate. The bladder is distended on rectal examination. In most fatal cases, a single large urolith, occasionally accompanied by smaller ones, is found in the bladder; less frequently, the urolith may be found lodged at the bladder neck or the ischial arch. Nephroliths are occasionally found via ultrasonography in horses with cystic calculi; owners of such horses should be informed that obstruction may recur.

Bilateral nephroliths are not uncommon in adult horses that have been used for performance. Intermittent chronic obstruction of ureters will eventually cause renal failure, resulting in weight loss and anorexia.

Diagnosis: Tentative diagnosis of urolithiasis is usually based on the history and clinical signs and confirmed most easily by rectal palpation of a firm, ovoid, intra-vesicular mass at or near the neck of the bladder. In most cases, urolith palpation is

not difficult, because clinical signs are rarely evident until the stone is several centimeters in diameter. Transrectal ultrasonography with a 7.5 MHz linear probe allows visualization of the stone. If ultrasound examination cannot be performed, the distended bladder should be catheterized to facilitate palpation and eliminate the possibility of urethroliths, urethral stricture, or smegma impaction of the urethral sinus. Urinalysis frequently reveals RBCs, neutrophils, calcium carbonate crystals, and proteinuria. Cystoscopy, ultrasonography, and radiology are not essential for detection of urocystoliths in horses but may provide additional diagnostic or prognostic information. Ultrasonography is necessary to identify nephroliths. Ureteroliths and cystic calculi can usually be palpated during rectal examination.

Treatment: Several surgical procedures have been described for urocystolith removal. Surgical options include midline or paramedian laparotomy and cystotomy, pararectal cystotomy, subischial urethrostomy, urethral sphincterotomy, and laser or shock wave lithotripsy. Selection of a procedure is dictated by the size, location, and number of uroliths; the sex and physiologic status of the horse; and the availability of surgical facilities. Bladder rupture, although uncommon in adult horses, may occur due to urethral obstruction or recumbency or after foaling in mares.

UROPERITONEUM IN FOALS

Uroperitoneum is defined as urine leakage into the peritoneal space. In foals, this most commonly results from tearing of the bladder during parturition, prolonged recumbency while being treated for a neonatal illness, or rupture of the urachus secondary to umbilical abscessation. Ureteral or urethral tears are rare. Some studies indicate a higher incidence of bladder rupture in males than in females, possibly because the narrower pelvis and the longer, narrower urethra of colts is a predisposing factor. Urachal rupture occurs both in males and females. Traumatic bladder rupture is thought to be caused by uterine contractions on a full bladder as the foal passes through the birth canal. Although most ruptured bladders at birth are thought to be traumatic, the presence of smooth edges and absence of hemorrhage around the tear in some foals might suggest a congenital origin (developmental defect of the bladder wall). Most bladder tears are located on the dorsum of the bladder. In the

case of a ruptured urachus, infection in the umbilical stump can weaken the urachal wall and result in leakage of urine into the abdomen or subcutaneously near the umbilicus. Prematurity, neonatal encephalopathy, cystitis, ascending infection, abdominal trauma, failure of passive transfer, and sepsis may predispose the foal to bladder rupture.

Clinical Findings: Foals generally appear normal at birth but progressively become lethargic, tachycardic, and tachypneic throughout 24–48 hr. Signs may not appear for a longer period in foals with a ruptured urachus. As the condition progresses, the abdomen becomes noticeably distended, and ballottement may produce a fluid wave. Most foals attempt to urinate often, with small amounts of urine being produced. This stranguria is often misinterpreted as straining to defecate. Other foals may be anuric or urinate normally.

Diagnosis: Ultrasonographic abdominal examination and blood and peritoneal fluid analysis can be helpful in diagnosis. Foals usually have a neutrophilic leukocytosis. Serum hyperkalemia combined with hyponatremia and hypochloremia are seen because of the high concentration of potassium and low levels of sodium and chloride in the urine, which rapidly equilibrate across the peritoneum. An ECG may show broad QRS complexes and very tall T waves due to hyperkalemia. The increased serum potassium predisposes the foal to bradycardia and cardiac arrhythmias (AV block, atrial standstill, and cardiac arrest) if not corrected. Serum BUN and creatinine values can be normal but usually are increased. Blood gas analysis may also be normal or reveal a metabolic acidosis. Abdominal fluid is pale yellow and copious and can easily be detected on ultrasonographic evaluation. The creatinine level in the peritoneal fluid is at least double that in the serum. This test is the most accurate in diagnosing the problem. If laboratory testing is not available, 10 mL of methylene blue can be injected into the bladder via a urinary catheter. If the bladder is patent to the peritoneal space, dye should be seen in the peritoneal fluid within 15 min.

The clinical signs of progressive depression and stranguria can confuse the diagnosis. Differential diagnoses include septicemia (*see* p 2089), hypoxic ischemic encephalopathy/neonatal encephalopathy (*see* p 2094), persistent meconium impaction (*see* p 2096), or colic (*see* p 248) for other reasons.

In the case of a urachal rupture, abdominal ultrasonography may be helpful to establish an etiologic diagnosis. Ultrasonography of the umbilical remnants may suggest the presence of infection or abscessation. A large amount of fluid in the abdomen is also seen. Rarely, neonatal foals may become azotemic because of rupture of one or both ureters. Accumulation of urine in the retroperitoneal area can be seen via ultrasound.

Treatment: Surgery is necessary to correct the defect and, in uncomplicated cases, is very successful. The foal should be stabilized before surgery. Potassium >6 mEq/L should be lowered preoperatively by either 500 mL of normal saline, sodium bicarbonate plus 10% dextrose throughout 30–40 min, or sodium bicarbonate administration alone. All of these treatments help drive potassium into cells. If the potassium is >8 mEq/L or the above treatments are unsuccessful, administration of insulin at 0.1 mg/kg, IV, in dextrose and saline and/or peritoneal fluid drainage can be considered.

The bladder should be repaired using absorbable sutures. Because surgical staples have migrated into the bladder and become the nidus for stone formation at a later date, they should not be used. If the umbilical structures are enlarged (indicating infection), they should be removed at the time of surgery and cultured. After surgical correction of the bladder, an indwelling urinary catheter may be placed for 48 hr to decrease bladder distention and leakage of urine at the repair site; however, this is rarely done on a first repair.

If a bladder rupture is recognized early in an otherwise healthy foal and the foal is stabilized appropriately before surgery, the prognosis for recovery is good to excellent, with success rates as high as 95%. In septic or premature foals, in which complications such as peritonitis, incisional complications, adhesions, and anesthetic death are encountered more frequently, the prognosis is fair. All recumbent foals should be considered at high risk of bladder rupture and may require prophylactic indwelling catheterization.

RENAL TUBULAR ACIDOSIS IN HORSES

Etiology: Type 1 renal tubular acidosis (RTA) is a sporadic disorder in horses. The RTA may be preceded by drug therapy for another condition or renal injury, or there may be no predisposing cause. RTA may be transient or recurring. Genetic predisposition is unproved but possible in some cases.

Clinical Findings and Diagnosis: Signs include acute onset of depression, anorexia, muscle trembling, and tachycardia and/or arrhythmia. There are many differential diagnoses for these clinical signs, so serum chemistry testing and urinalysis are necessary. There is a severe metabolic acidosis, marked hyperchloremia, and hypokalemia with equine RTA. The urine pH is neutral to alkaline.

Treatment: Administration of sodium bicarbonate IV and PO is generally successful in correcting the metabolic acidosis. Potassium supplementation may be critical if the serum potassium concentration is <2.5 mEq/L or if the horse is trembling or has cardiac arrhythmias. Treatment throughout a few days may result in complete resolution in some horses, but others may require continued supplementation with sodium bicarbonate administered PO.

URETHRAL DEFECTS CAUSING HEMATURIA IN ADULT MALE HORSES

Etiology: The cause of the urethral defects is not proved, but they are believed to occur because of high pressure in the corpus spongiosum at the end of urination in geldings or during ejaculation in stallions.

Endoscopic examination of the urethra of an adult Quarter Horse gelding that had hematuria at the end of urination. The defect in the urethra is dorsal and at the level of the ischial arch. *Courtesy of Dr. Thomas J. Divers.*

This high pressure may cause a “blow-out” tear in the urethral mucosa.

Clinical Findings and Diagnosis:

The clinical signs are limited to hematuria at the end of urination, associated with contractions of the bulbourethral muscle in geldings or with hemospermia and decreased fertility in stallions. All breeds may be affected, although the disorder seems more common in Quarter horses.

Diagnosis is based on clinical signs and urethral endoscopic findings. The urethral

defect is seen in most cases on the dorsal convex surface of the urethra at the level of the ischial arch.

Treatment: Some cases may heal spontaneously, but most continue with intermittent hemorrhage; anemia is rare. Breeding rest is recommended for stallions. Subischial urethrostomy or subischial incision into the spongiosum penis reduces vascular pressure in the corpus spongiosum during urination, allowing the defect to heal. A buccal mucosal graft was used to repair the defect in a stallion.

INFECTIOUS DISEASES OF THE URINARY SYSTEM IN SMALL ANIMALS

Most infectious diseases of the urinary system in small animals are aerobic bacterial infections. Common organisms include *Escherichia coli*, *Staphylococcus*, *Enterococcus*, and *Streptococcus*. Less common organisms causing infection include *Klebsiella*, *Proteus*, and *Pseudomonas*. *Pasteurella* is more common in cats than dogs. *Mycoplasma* is an uncommon cause of urinary tract infection and is usually found as a coinfection with bacteria. Leptospirosis is a worldwide zoonotic disease caused by filamentous bacteria that infect the kidney and many other organs. Fungi, yeast, and parasites uncommonly infect the urinary system.

Bacterial infections of the urinary tract typically ascend from the urethra into the bladder and in some cases into the kidneys. Predisposing factors include abnormalities of urine flow (eg, urine retention), decreased urothelial defense mechanisms, decreased systemic immune defense mechanisms, or inadequate urine concentration. Female dogs are more susceptible to urinary tract infections than male dogs, except for bacterial prostatitis in older, uncastrated male dogs. Dogs with concurrent diseases (eg, chronic kidney disease or hyperadrenocorticism) are at greater risk. Cats are relatively resistant to bacterial cystitis compared with dogs. Less than 2% of cats 1–10 yr old with lower urinary tract signs have a positive culture for bacterial infection. Adults cats with clinical signs of lower urinary tract pain and inflammation typically have a noninfectious

cause, such as idiopathic cystitis, interstitial cystitis, or urinary bladder stones. Geriatric cats, immunosuppressed cats, or those with systemic diseases (eg, chronic kidney disease, hyperthyroidism) are more prone to bacterial urinary tract infections. Urinary tract pathogens, except for *Leptospira interrogans*, are not considered zoonotic. However, the potential for multidrug-resistant bacteria to localize in the urinary system is a concern for both animal and human health. Subtherapeutic treatment regimens and inappropriate antibiotic selection are contributing factors. Animals that receive chronic antibiotic treatment or are immunocompromised may (rarely) become infected with *Candida* spp. Systemic fungal infections (eg, blastomycosis, aspergillosis, protothecosis) can involve the urinary system; the kidneys and prostate are the most likely sites.

BACTERIAL CYSTITIS

Bacterial cystitis is infection and inflammation of the urinary bladder. Clinical signs are pollakiuria, hematuria, dysuria, and urinating in inappropriate places. Hematuria may be more noticeable at the end of the urine stream. An animal may exhibit pain on palpation of the caudal abdomen, and the bladder may feel thickened or irregular. Bacterial cystitis is occasionally diagnosed in an asymptomatic animal when a routine urinalysis is performed. Chronic glucocorticoid administration, hyperadrenocorticism, chronic kidney disease, and diabetes

mellitus may be associated with asymptomatic urinary tract infections. Occasionally, animals with no concurrent disease will have bacteria in the urine without evidence of a true infection (ie, bladder mucosal invasion and inflammation); this condition is termed asymptomatic bacteriuria.

Urinalysis often shows increased protein and hemoglobin on the urine dipstick analysis. The WBC part of the dipstick (ie, nitrate) is inaccurate in dogs and cats and should not be used. The urine pH may be alkaline (7.5–9) if the bacteria are urease positive (eg, *Staphylococcus* or *Proteus*). However, an alkaline urine pH by itself is not abnormal, because diet and other factors can affect urine pH. Urine sediment should be examined microscopically. Increased numbers of WBCs, RBCs, and/or bacteria are consistent with cystitis. Bacteria can be confused with stain precipitate; filtering the stain or evaluating the sediment without staining is advised. Lack of visible bacteria in the sediment does not exclude urinary tract infection.

If clinical signs and/or urinalysis are suggestive of infection, a urine culture and antimicrobial susceptibility test should be performed. Cystocentesis is the preferred method for sample collection, followed by sterile urethral catheterization or a midstream free catch into a sterile collection cup. A quantitative culture is necessary to interpret the result, unless the sample was collected by cystocentesis. Ideally, the culture should be set up within 2 hr of collection. If the laboratory is off-site, the sample should be refrigerated and processed by the laboratory within 24 hr. If the specimen cannot be refrigerated, commercial collection kits that contain preservatives can be used to maintain a stable bacterial population at room temperature for 24 hr. Laboratories that can provide both quantitative culturing and a minimum inhibitory concentration–based method for antimicrobial susceptibility testing are preferred.

Antibiotic regimens for infections involving soft tissues, such as bacterial cystitis with prostatic involvement, should be similar to pyelonephritis (see below). Simple bacterial cystitis is treated for 2 wk with a broad-spectrum antibiotic that achieves a high concentration in the urine. Appropriate initial choices include amoxicillin (10–20 mg/kg, PO, bid-tid), cefadroxil (22–30 mg/kg, PO, bid), cefpodoxime (5–10 mg/kg/day, FDA approved for dogs only), ormetoprim-sulfadimethoxine (27 mg/kg, PO, day one, then 13.5 mg/kg/day, PO), or cefovecin (8 mg/kg,

SC, day one, which may be repeated once 7 days later). A repeat urine culture 3–7 days after oral therapy or on day 21 if cefovecin is used is recommended. If positive, another antibiotic based on the new susceptibility test results is given for a longer treatment period (eg, 3–4 wk). Very resistant or recurrent infections should be treated for 4–6 wk. Every course of treatment should be followed by a urine culture, even if the signs have resolved. In animals that have a history of chronic or recurrent infections, a urine culture should be done 3–7 days and 3 mo after successful therapy. If both of these cultures are negative, then a urine culture should be repeated at 6 and 12 mo after therapy. Because resistance to antibiotics can develop during therapy, antimicrobial susceptibility testing should be performed on every positive urine culture.

Animals with recurrent bacterial cystitis should be evaluated for an underlying cause. A recurrent infection caused by the same bacterial organism is termed a relapse and is essentially a treatment failure. This is typically caused by inappropriate antibiotic therapy (ie, wrong drug, dosage, or treatment duration) and often occurs because of an unrecognized complicating factor (eg, deep-seated bladder wall infection, bladder polyps, renal or prostatic involvement, concurrent disease). A recurrent infection in which different organisms are causative is termed a reinfection and is usually caused by host defense problems such as disorders of micturition (eg, urethral incompetence), anatomic abnormalities (eg, hooded vulva, patent urachus, ectopic ureters, uroliths), and/or concurrent disease (eg, chronic kidney disease, hyperadrenocorticism, chronic glucocorticoid administration). Abdominal radiographs are frequently diagnostic for uroliths but negative survey films should be followed by ultrasonography, cystoscopy, and/or double-contrast cystourethrography to exclude radiolucent urocystoliths, anatomic defects, polyps, and neoplasia. The history may reveal chronic glucocorticoid use. A serum biochemical profile, CBC, and complete urinalysis are important to exclude predisposing systemic diseases, such as chronic kidney disease, hyperadrenocorticism, and diabetes mellitus. Other diagnostic considerations include feline immunodeficiency virus, feline leukemia virus, and hyperthyroidism in cats or hyperadrenocorticism in dogs.

In cases that respond to therapy but continue to have frequent bouts of cystitis without an identifiable cause, low-dose prophylactic antibiotics can be used to

prevent ascending bacteria from establishing an infection according to the following protocol: 1) a therapeutic course of an antibiotic for the current infection is completed, 2) no antibiotics are given for 3 days, to allow collection of urine for a culture after treatment, and 3) the prophylactic protocol is immediately started. Prophylaxis consists of using a broad-spectrum antibiotic (eg, amoxicillin, cefadroxil) at one-third of the total daily dose, given at bedtime, indefinitely. Every 6–8 wk, the antibiotic should be stopped for 3–7 days to obtain a sample for repeat urinalysis and culture. Every new infection should be treated with a therapeutic course of an antibiotic based on culture and susceptibility results. The treatment antibiotic will likely be different than the prophylactic antibiotic. Oral cranberry extract and D-mannose may be useful adjuncts. The most valuable therapeutic antibiotics (eg, fluoroquinolones, second- or third-generation cephalosporins) should be reserved for resistant infections. If the recurrent infection is resistant to the prophylactic antibiotic, this antibiotic can still be used for future prophylaxis after the infection is eradicated. Encouraging frequent voiding during the daytime is helpful to prevent recurrent infections. The major disadvantage of using a prophylactic antibiotic protocol is development of multidrug-resistant bacteria.

PYELONEPHRITIS

Kidney infection (pyelonephritis) is usually due to ascending bacteria, although hematogenous spread is possible. The organisms and predisposing causes are similar to those of bacterial cystitis. Renoliths and ureteroliths, which impede the normal flow of urine out of the renal pelvis, may be contributory. Animals at risk of pyelonephritis are the very young, the very old, the immunosuppressed, or those with inadequate urine-concentrating ability. In many instances, an underlying cause is not identified. Virulence factors associated with specific bacterial strains play a role in allowing colonization of the urothelium, especially with pyelonephritis caused by *Escherichia coli*. The fact that pyelonephritis is usually ascending and bilateral suggests that these virulence factors are more important than previously recognized.

Animals with acute pyelonephritis may exhibit kidney or flank pain, fever, malaise, and sometimes vomiting, polyuria, and polydipsia. Urinalysis shows proteinuria, pyuria, bacteriuria, and/or hematuria. WBC

casts may be present in fresh urine sediment. The urine culture is usually positive; the CBC may show leukocytosis with a left shift. The biochemical profile may be normal or show azotemia (prerenal or renal) and/or hyperglobulinemia. The animal may be in kidney failure. Chronic pyelonephritis is more difficult to recognize, because clinical signs may be subtle or absent. Polyuria and polydipsia are frequent. In many cases, the disease goes unrecognized until kidney failure occurs. Although abnormalities in the urinalysis are present, they are often less dramatic than with acute kidney infection. A single urine culture can be negative if bacterial numbers are low. Other useful diagnostic tests include abdominal ultrasonography and IV pyelography. Both studies may show dilation of one or both renal pelvises secondary to inflammation and partial obstruction. Asymmetric renal size and architectural changes with renal pelvic dilation is highly suggestive of chronic pyelonephritis. In some cases, nephropylcentesis via ultrasonographic guidance is useful to obtain a sample of urine from the dilated renal pelvis for analysis and culture.

Pyelonephritis should be treated aggressively with broad-spectrum antibiotics, based on urine culture and antimicrobial susceptibility testing, for 4–8 wk. The infection may respond to the same antibiotics recommended for cystitis, but more frequent administration (eg, amoxicillin tid rather than bid) and/or higher dosages are indicated. A fluoroquinolone or a combination of a fluoroquinolone with a β -lactam antibiotic is often effective. Dosages should be the same as for other soft-tissue infections. Animals that are febrile, anorectic, dehydrated, or azotemic should be hospitalized to provide IV antibiotics and fluid therapy. Fluid therapy may prevent acute pyelonephritis from progressing to azotemic acute kidney injury and will improve renal perfusion and uremic signs in animals already experiencing uremia. Animals with acute pyelonephritis may recover normal renal function, depending on the amount of damage that occurred before treatment. In cases of chronic pyelonephritis with a severely hydronephrotic, nonfunctional kidney, a nephrectomy may be the treatment of choice once the animal has been stabilized. This will remove the source of infection and hopefully save the opposite kidney. IV pyelography and/or renal scintigraphy are useful to assess the relative function of each kidney. If both kidneys are severely

affected, medical management alone is the only alternative. Recovery to chronic, stable renal failure is possible in many cases.

The urine should be cultured during the first 5–7 days of therapy to assess antibiotic efficacy. A urinalysis and culture should be repeated 3–7 days after therapy, and then monthly for 3 consecutive months. If all of these cultures are negative, the interval between urine cultures may be gradually lengthened. Animals with pyelonephritis are at high risk of persistence or recurrence of infection and for secondary infections at other sites (eg, bacterial endocarditis and discospondylitis).

INTERSTITIAL NEPHRITIS, GLOMERULONEPHRITIS, AND VASCULITIS

Acute interstitial nephritis in dogs is caused most often by *Leptospira interrogans* (see p 650). Cats rarely develop leptospirosis, and clinical signs are less severe than in dogs. Other infectious causes of nephritis in dogs include *Leishmania donovani* and *Borrelia burgdorferi*. These systemic vectorborne diseases are endemic in specific geographic areas. Glomerulonephritis is the predominant renal pathology, so these are considered immune complex diseases rather than true urinary tract infections. Toxoplasmosis can cause pyogranulomas in the kidneys or elsewhere in the urinary system. Systemic infectious diseases that cause vasculitis in cats or dogs (eg, feline infectious peritonitis, Rocky Mountain spotted fever) may also cause kidney disease.

CAPILLARIA PLICA INFECTION

Capillaria plica may infect the urinary bladder, and occasionally the ureters and renal pelvises, of dogs and cats. Distribution is worldwide, and wild animals appear to be the primary hosts. A similar but less common organism, *C. felis cati*, is also found in cats. Dogs and cats become infected by eating earthworms that contain the first-stage larvae. Mature *Capillaria* are threadlike, yellowish, and 13–60 mm long. The eggs are colorless, operculated, have a slightly pitted shell, and are 63–68 × 24–27 µm in size. Most dogs and cats are asymptomatic. Some animals show signs of pollakiuria, urinary incontinence, and urinating in abnormal places. The eggs are shed in the urine and may be found in the urine sediment. Microscopic hematuria and increased numbers of epithelial cells may also be present. Reported treatments

include levamisole, fenbendazole, albendazole, and ivermectin. The treatment of choice is unknown, but a single dose of ivermectin at 0.2 mg/kg, SC, is likely to be effective. It is not FDA approved for this use and is contraindicated in Collie breeds. The parasite may be self-limiting in the absence of reinfection.

GIANT KIDNEY WORM INFECTION IN MINK AND DOGS

Mink are the most common definitive host for *Dioctophyma renale*, the largest known nematode, which has a worldwide distribution. Many other species, including dogs and people, can become infected. The definitive host contracts the parasite by ingesting encysted larvae in raw fish (eg, pike, bullhead) or frogs or by ingesting an infected annelid worm. The larvae penetrate the bowel wall and migrate first to the liver and later to the kidneys. In dogs, the parasite often fails to reach the kidneys and may be found free in the abdominal cavity. Kidney worms grow larger in dogs than in mink, reaching up to 103 cm.

Female worms are larger than male worms, and both are blood red. Both male and female worms must be present in the same kidney to complete the life cycle. Barrel-shaped, yellow-brown eggs with a thick, pitted shell measuring 71–84 × 45–52 µm are shed into the urine.

In the kidneys, the worm(s) cause obstruction, hydronephrosis, and destruction of the renal parenchyma. The right kidney is most commonly affected. Kidney failure can result if both kidneys are parasitized. Chronic peritonitis, adhesions, and liver disease are also possible. Clinical signs are hematuria, pollakiuria, weight loss, and renal or abdominal pain. Urinalysis may reveal proteinuria, hematuria, and pyuria. Ultrasonography or IV pyelography shows the enlarged hydronephrotic kidney(s). The diagnosis is made by finding the eggs in the urine sediment if both sexes of the nematode are present in the kidney and the ureter is patent. Alternatively, exploratory laparotomy may reveal the diagnosis. Worms may be found in the peritoneal cavity, between the lobes of the liver, or within the affected kidney(s) via nephrotomy.

Unilateral nephrectomy is the treatment of choice if the opposite kidney is unaffected. Preventing ingestion of raw fish or other aquatic organisms is recommended in areas where the parasite is known to infect wild animals.

NONINFECTIOUS DISEASES OF THE URINARY SYSTEM IN SMALL ANIMALS

RENAL DYSFUNCTION

Failure of the filtration function of the kidneys leads to the development of azotemia (an excess of nitrogenous compounds in the blood), which may be classified as prerenal, renal, postrenal, or of mixed origin. Prerenal azotemia develops whenever mean systemic arterial blood pressure declines to values <60 mmHg and/or when dehydration causes plasma protein concentration to increase. Conditions that may lead to development of prerenal azotemia include dehydration, congestive heart failure, and shock. Prerenal azotemia generally resolves with appropriate treatment, because kidney structure has not been altered, which allows normal function to resume once renal perfusion has been restored. Renal azotemia refers to a reduction in glomerular filtration rate (GFR) of ~75% during acute or chronic primary renal (or intrarenal) diseases. Postrenal azotemia develops when the integrity of the urinary tract is disrupted (eg, bladder rupture) or urine outflow is obstructed (eg, urethral or bilateral ureteral obstruction). Once adequate urine flow is restored, postrenal azotemia will resolve.

Chronic Kidney Disease

Chronic kidney disease (CKD) involves a loss of functional renal tissue due to a prolonged (≥ 2 mo), usually progressive, process. Dramatic changes in renal structure may be seen, although structural and functional changes in the kidney are only loosely correlated. CKD often smolders for many

months or years before it becomes clinically apparent, and it is invariably irreversible and frequently progressive. Although congenital disease results in a transient increase in prevalence in animals <3 yr old, the prevalence increases with advancing age from 5–6 yr. In geriatric populations at referral institutions, CKD affects as many as 10% of dogs and 35% of cats. The prevalence in the general small animal population is likely to be lower, perhaps 1%–3%. Several breeds of dogs and cats are associated with heritable CKD (*see* p 1496). There is no apparent breed or sex predisposition for nonheritable CKD in dogs or cats.

CKD is generally classified into various stages (*see* TABLE 2) based on laboratory tests and clinical signs. In Stage 1, a process is damaging the kidneys but azotemia and clinical signs have not developed. Unfortunately, renal disease is uncommonly detected at this stage. In Stage 2, the disease has progressed, GFR has fallen to $<25\%$ of normal, and azotemia is present, but clinical signs are not yet seen. However, this stage may be associated with impaired urine-concentrating ability and increased urine volume. Stage 3 occurs when GFR has declined further, azotemia is present, and clinical signs are often seen. Stage 4 reflects further progression and severe azotemia, with clinical signs present. This staging system applies to CKD only.

Substaging Based on Blood Pressure:

Systemic hypertension is present in ~20% of dogs and cats with CKD and is associated with target organ damage in the kidneys,

TABLE 2 CLASSIFICATION OF STAGES OF KIDNEY DISEASE

Stage ^a	1	2	3	4
	Nonazotemic Kidney Disease	Mild Renal Azotemia	Moderate Renal Azotemia	Severe Renal Azotemia
Creatinine (mg/dL)				
Dogs	<1.4	1.4–2.0	2.1–5.0	>5.0
Cats	<1.6	1.6–2.8	2.9–5.0	>5.0

^a Stages are as recommended by the International Renal Interest Society.

TABLE 3

SUBSTAGES OF CHRONIC KIDNEY DISEASE BASED ON ARTERIAL BLOOD PRESSURE (AP) MEASUREMENTS AND RISK OF TARGET ORGAN DAMAGE

Substage ^a	AP0	AP1	AP2	AP3
	No or minimal risk	Low risk	Moderate risk	High risk
Blood pressure (mmHg)				
Systolic	<150	150–159	160–179	>180
Diastolic	<95	95–99	100–119	>120

^a Substages are as recommended by the International Renal Interest Society. Other modifiers that may be added to the AP substage: C = evidence of end organ damage or complications present; T = patient presently being treated.

eyes, CNS, and cardiovascular system. It is recommended that animals with CKD be substage on the basis of blood pressure measurements (see TABLE 3).

In general, animals in substage AP3 and those in substage AP2 with preexisting target organ damage (eg, retinal injury or CKD) should be considered candidates for antihypertensive therapy.

Substaging Based on Proteinuria:

The routine dipstick evaluation of urine for protein is not particularly specific, because many of the positive reactions ($\frac{1}{2}$ in dogs and $\frac{1}{2}$ in cats) are false-positives. Although it is a useful screening test, a positive result should be followed with a more specific test, such as the sulfosalicylic acid test, the urine protein:creatinine ratio, or albumin-specific assays.

Species-specific antibodies for albumin have led to development of highly specific and sensitive assays for the detection and measurement of urine albumin concentrations. Microalbuminuria is defined as a urine protein content that leads to a negative reaction for the routine urine dipstick and a positive reaction with a

species-specific antibody test. Animals with microalbuminuria frequently exhibit or subsequently develop kidney disease, systemic inflammatory or metabolic disease, neoplasia, or infectious diseases.

Proteinuria is an important finding and is associated with a poor prognosis in aged animals and in those with CKD. Changes in the magnitude of proteinuria represent a good marker for the efficacy of antihypertensive therapy. Animals with CKD should also be substage on the basis of proteinuria (see TABLE 4), using the protein:creatinine ratio.

Etiology: Attempting to identify the primary process causing the kidney disease, especially in Stages 1 and 2, is important to form a prognosis and treatment plan. Known causes of CKD include diseases of the macrovascular compartment (eg, systemic hypertension, coagulopathies, chronic hypoperfusion), microvascular compartment (eg, systemic and glomerular hypertension, glomerulonephritis, developmental disorders, congenital collagen defects, arylodiosis), interstitial compartment (eg, pyelonephritis, neoplasia,

TABLE 4

SUBSTAGES OF CHRONIC KIDNEY DISEASE BASED ON PROTEINURIA

Substage ^a	N	BP	P
	Nonproteinuric	Borderline	Proteinuric
Dogs	<0.2 ^b	0.2–0.5	>0.5
Cats	<0.2	0.2–0.4	>0.4

^b Urine protein:creatinine ratio

obstructive uropathy, allergic and immune-mediated nephritis), and tubular compartment (eg, tubular reabsorptive defects, chronic low-grade nephrotoxicity, obstructive uropathy). Many causes of chronic, generalized renal disease are associated with progressive interstitial fibrosis. The severity of interstitial fibrosis is positively correlated with the magnitude of decline of GFR and negatively correlated with the prognosis. The glomerular, tubulointerstitial, and vascular lesions found in animals with generalized CKD are often similar, regardless of the initiating cause, particularly in Stage 4. At this point, renal histology may show only marked interstitial fibrosis, which may be called chronic interstitial nephritis or tubulointerstitial fibrosis. This term describes the morphologic appearance of kidneys with end-stage chronic disease of any cause. Because acute kidney injury may progress to a chronic condition, any cause of acute kidney injury is also a possible cause of CKD.

Clinical Findings: Generally, no clinical signs are seen as a direct result of disease until $\geq 75\%$ of nephron function has been impaired (Stages 3 and 4). Exceptions are chronic kidney diseases that develop as part of a systemic disease with clinical signs referable to involvement of other body tissues (eg, systemic lupus erythematosus, systemic hypertension), chronic kidney diseases accompanied by nephrotic syndrome, or those associated with marked renal inflammation and capsular swelling leading to flank pain and occasionally to vomiting. Usually, the earliest clinical signs commonly attributable to renal dysfunction are polydipsia and polyuria, which are not seen until the function of approximately two-thirds of the nephrons has been impaired (late Stage 2 or early Stage 3). Further destruction of renal tissue leads to azotemia without new clinical signs in Stage 2, and finally to the clinically apparent uremic syndrome in Stage 4. Initially, uremia is associated with occasional vomiting and lethargy. As the disease progresses within Stages 3 and 4 throughout months (dogs) to years (cats), anorexia, weight loss, dehydration, oral ulceration, vomiting, and diarrhea become fully manifest. Loose teeth, deformable maxilla and mandible, or pathologic fractures may be seen with renal secondary osteodystrophy (see p 1056), but these are uncommon and generally seen only in young dogs with end-stage congenital renal disease. Physical examination and imaging studies of animals

in Stages 3 and 4 usually reveal small, irregular kidneys, although normal to large kidneys can be seen in animals with neoplasms, hydronephrosis, or glomerulonephritis. Mucous membranes are pale in late Stage 3 and Stage 4, due to the presence of a nonregenerative, normocytic, normochromic anemia.

Diagnosis: In Stages 1 and 2, diagnosis is often missed or made incidentally during imaging studies or urinalyses conducted for other purposes. In Stages 3 and 4, the BUN, serum creatinine, and inorganic phosphorus concentrations are increased. Potassium depletion, due to renal potassium wasting combined with inadequate intake and the kaliuretic effects of acidosis, is frequently seen in cats and occasionally in dogs. Hyperkalemia associated with oliguria and anuria may be noted in terminal Stage 4 or whenever marked prerenal azotemia is concurrent with CKD. Systemic hypertension and associated complications develop in ~20% of affected cats and dogs and can occur at any stage. Osteoporosis may be seen radiographically, although this late finding is generally not helpful for diagnosis.

The urine specific gravity may range from 1.001–1.060 in dogs and 1.005–1.080 in cats, depending on body needs for water homeostasis; the normal range overlaps the abnormal or inappropriate range. In animals with dehydration and normal renal function, urine specific gravity should be >1.030 in dogs and >1.035 in cats. The inability to produce concentrated urine when challenged by dehydration is an early sign of CKD; however, dogs with primary glomerular disease, and some cats, may become azotemic while retaining the ability to concentrate urine to a specific gravity >1.035 . Even so, concentrated urine is rarely seen when the serum creatinine is >4 mg/dL in an animal with azotemia of renal origin.

The polydipsia and polyuria of CKD must be differentiated from diseases that cause primary polydipsia (eg, psychogenic polydipsia, hyperthyroidism) or interfere directly with the urine-concentrating mechanism. This includes conditions that lead to retention of solute in tubular fluid (eg, diuretic administration, diabetes mellitus), central diabetes insipidus, and nephrogenic diabetes insipidus (eg, hyperadrenocorticism, hypercalcemia, pyometra, diseases causing septicemia). Adrenal insufficiency leads to a urine-concentrating defect and may thus be confused with Stage 2 and 3 renal disease, because prerenal azotemia may be caused by the vomiting, diarrhea, and polydipsia

associated with hypoadrenocorticism. Hyperkalemia, hyponatremia, and/or reduced plasma Na^+ to K^+ ratio helps establish a tentative diagnosis of adrenal insufficiency, which must be confirmed by hormonal assay(s). Also, animals with hypoadrenocorticism improve rapidly in response to proper therapy.

Combinations of survey radiography, abdominal ultrasonography, serial clinical pathology tests, including urinalyses and urine cultures, and blood pressure measurements should be performed to evaluate the severity of disease, establish a prognosis, monitor the response to therapy, and identify complicating factors. Specific renal function tests and renal biopsy may be helpful to identify the exact cause in Stages 1–3, but the presence of advanced pathologic changes in Stage 4 is nonspecific and often precludes identification of an underlying cause by histologic studies. This condition in late Stage 4 is often described as end-stage renal failure clinically and as chronic, generalized nephritis pathologically. CKD should be distinguished from the more readily reversible acute disease. Frequently, differentiation may be accomplished with an appropriate history, physical examination, and laboratory findings, although a renal biopsy may be required. However, therapy for CKD caused by a range of morphologic lesions is similar, so renal biopsies may not be warranted unless marked proteinuria is present or a treatable cause is suspected.

Treatment: With appropriate therapy, animals can survive for long periods with only a small fraction of functional renal tissue, perhaps 5%–8% in dogs and cats. Recommended treatment varies with the stage of the disease. In **Stages 1 and 2**, animals usually have minimal clinical abnormalities. Efforts to identify and treat the primary cause of the disease should be thorough. The identification and supportive treatment of developing complications (eg, systemic hypertension, potassium homeostasis disorders, metabolic acidosis, bacterial urinary tract infection) should be aggressively pursued. The systemic hypertension seen in ~20% of animals with CKD may be seen at any stage and is not effectively controlled by feeding a low-salt diet. The usual antihypertensive medications for blood pressure substages AP2 and AP3 (see TABLE 3) are a calcium-channel blocker such as amlodipine besylate (0.25–0.5 mg/kg/day, PO) or an angiotensin-converting enzyme (ACE) inhibitor such as enalapril or benazepril (0.5 mg/kg, once

daily in cats and bid in dogs) or an angiotensin-receptor blocker (ARB) such as telmisartan (1 mg/kg, once daily in cats and bid in dogs). If an ACE inhibitor is used in conjunction with a renal diet, potassium should be carefully monitored. Hyperkalemia may develop, particularly in Stage 4, and dietary change or dosage adjustment should be considered if serum potassium exceeds 6.5 mEq/L. While ACE inhibitors (or ARBs) and calcium-channel blockers may be administered together, a calcium-channel blocker is usually recommended as initial therapy in cats and an ACE inhibitor (or ARB) in dogs. In addition to providing a continuous supply of fresh drinking water and encouraging (and documenting) adequate dietary intake, body condition scoring should be used routinely to assess adequacy of intake. Animals in this stage should be fed standard, commercially available maintenance diets, unless they are markedly proteinuric (see below). All affected animals should be reevaluated every 6–12 mo, or sooner if problems develop.

In **Stages 2 and 3**, the principles for management of complications are the same, except that the animal should be evaluated every 3–6 mo. These evaluations should include hematology, serum biochemistries, and urinalysis. Because dogs and cats with CKD are prone to development of bacterial urinary tract infections, urine culture should be performed annually and any time urinalysis suggests infection. The progressive nature of this disease produces a vicious cycle of progressive renal destruction. Measures that may slow this progression include dietary phosphorus restriction, dietary fish oil supplementation, antihypertensive agents (for hypertensive dogs and cats), and administration of ACE inhibitors or ARBs (proteinuria substage P; see TABLE 4). Dietary restriction of phosphate and acid load is essential in this stage, and specialized diets for management of kidney disease should be fed. Potassium citrate or sodium bicarbonate, given PO, may be indicated if the animal is severely acidotic (plasma bicarbonate <15 mEq/L) or remains acidotic 2–3 wk after diet change. If dietary restriction of phosphorus is unsuccessful in maintaining a normal level of serum phosphorus within 2–3 mo, phosphate-binding gels containing calcium acetate, calcium carbonate, calcium carbonate plus chitosan, lanthanum carbonate, or aluminum hydroxide should be administered with meals to achieve the desired effect. There is also a clear rationale for the inclusion of dietary n-3 polyunsaturated fatty acids in these stages.

In **late Stage 3 and Stage 4**, all of the principles of managing the preceding stages apply, except that the animal should be evaluated every 1–3 mo. Dietary restriction of protein may relieve some of the signs of uremia. High-quality protein (eg, egg protein) should be fed at a level of 2–2.8 g/kg/day for dogs and 2.8–3.8 g/kg/day for cats. Commercial diets formulated for cats and dogs with CKD generally meet this recommendation. Administration of a proton pump inhibitor such as omeprazole (0.5–1 mg/kg/day, PO) or an H₂-receptor antagonist such as famotidine (5 mg/kg, PO, tid-qid) decreases gastric acidity and vomiting. Anabolic steroids, such as oxymethalone or nandrolone, have been administered to stimulate RBC production in anemic animals, but this is not effective.

Recombinant erythropoietin and other erythropoiesis-stimulating agents (eg, darbopoietin, continuous erythropoietin receptor activator) may stimulate RBC production, but antierythropoietin antibodies develop in ~50% of animals treated with the human recombinant erythropoietin, epoetin alfa, and may result in refractory anemia. Darbopoietin may be less likely to produce this effect and may be preferred. Until species-specific products become generally available, erythropoietin administration is now recommended only for animals with clinically apparent signs of anemia (eg, weakness, marked lethargy not attributable to other factors), which generally occurs at a hematocrit <20%.

Fluid therapy with polyionic solutions, given IV or SC in the hospital or SC by owners at home, is often beneficial in animals with intermittent signs of uremia. Oral vitamin D administration may reduce uremic signs and prolong survival, particularly in dogs. However, vitamin D administration requires prior resolution of hyperphosphatemia (goal is serum phosphorus <6 mg/dL), and it may induce hypercalcemia. Probiotic medications and certain dietary fibers may enhance gut catabolism of nitrogenous compounds and uremic toxins. Feeding tubes may help manage chronic anorexia. Euthanasia or renal replacement therapy (renal transplantation and/or dialysis) should be carefully considered if therapy does not improve renal function and alleviate signs of uremia.

Acute Kidney Injury

Because not all animals with acute kidney injury (AKI) will be identified or exhibit azotemia, AKI has replaced the older term, acute renal failure. Animals with AKI are

most often presented to the veterinarian when a sudden, major insult damages the kidneys. The principal causes are toxins (eg, ethylene glycol, aminoglycoside antibiotics, hypercalcemia, hemoglobinuria, melamine-cyanuric acid, grapes or raisins, NSAIDs), ischemia (eg, embolic showers from disseminated intravascular coagulation or severe prolonged hypoperfusion), and infection (eg, leptospirosis, borreliosis).

Clinical Findings: Mild AKI often goes unrecognized; severe initial or repeated bouts may lead to CKD. Most often, AKI is recognized in advanced stages and is characterized clinically by anorexia, depression, dehydration, oral ulceration, vomiting and/or diarrhea, or oliguria. Physical examination findings often reveal dehydration but otherwise are usually not remarkable, although pain is occasionally elicited on palpation of the kidneys, which may be normal in size to slightly enlarged.

Diagnosis: A history of hypotension, shock, or recent exposure to known nephrotoxins in an animal with sudden-onset uremia is the typical clinical picture of an animal with acute kidney disease. The presence of poorly concentrated urine (specific gravity 1.007–1.030) despite dehydration and/or azotemia suggests renal dysfunction. Differentiating between chronic and acute kidney disease (and establishing a specific cause in acute kidney disease) is important, because the prognosis and specific therapy may differ. Animals with AKI usually have a compatible history and other urinalysis abnormalities; marked cylindruria is a frequent and definitive finding. Other urinalysis findings may include the presence of a large number of renal epithelial cells and leukocytes in the urine sediment, glucosuria, crystalluria, enzymuria, and/or myoglobinuria/hemoglobinuria. Animals with AKI generally have increased serum urea nitrogen, creatinine, and inorganic phosphorus concentrations and metabolic acidosis. Oliguria or anuria after rehydration, which is often associated with hyperkalemia, is a poor prognostic sign; in contrast, polyuric animals have a better prognosis, although they may become hypokalemic. The kidneys are typically normal in size and shape and an anemia is often, but not always, absent—findings that may help differentiate acute from chronic kidney disease.

After injury, the kidney has considerable potential for functional regeneration through the process of compensatory hypertrophy and adaptive hyperfunction. In animals with CKD, it is likely that most

of this regenerative process has occurred before the initial diagnosis. In contrast, animals with AKI have considerably more potential for improvement of renal function, if they can be sustained through a uremic episode. The duration of the uremic episode may be substantial with some nephrotoxins (eg, 1–3 wk with aminoglycoside antibiotics and 4–8 wk with ethylene glycol). A renal biopsy may be of value in assessment of the severity, extent, cause, and potential reversibility of the disease.

As a disease process, AKI is a spectrum, and the International Renal Interest Society recommends that patients with AKI be categorized primarily on the basis of serum creatinine. Animals with Grade I AKI have nonazotemic AKI (serum creatinine ≤ 1.6 mg/dL). Animals with Grades II–V AKI exhibit varying degrees of azotemia, with serum creatinine levels of 1.7–2.5 mg/dL in Grade II, 2.6–5 mg/dL in Grade III, 5.1–10 mg/dL in Grade IV, and >10 mg/dL in Grade V.

Treatment: Severe AKI that necessitates medical intervention is a serious condition, with a survival rate of ~50%. If the cause is known, specific therapy should be instituted, eg, 4-methylpyrazole or ethanol for ethylene glycol toxicity in dogs (see p 3046). Fluid therapy is indicated for all dehydrated and inappetent animals. A polyionic fluid such as lactated Ringer's solution is satisfactory unless hyperkalemia is present, in which case normal saline is recommended. Sodium bicarbonate may be cautiously added to the fluids to correct acidosis.

In oliguric or anuric animals, therapy to promote increased urine volume is often recommended if the animal is well hydrated and urine production is <0.5 mL/kg/hr. This approach has been questioned because urine flow may increase without corresponding increases in renal blood flow and GFR. Administration of excess fluid to an animal in the maintenance phase of oliguric renal failure may result in life-threatening pulmonary and cerebral edema. Nonetheless, efforts to increase renal blood flow and GFR may enhance urine production and do have a role in the management of these animals. For this therapy, urine production must be quantitatively monitored closely via an indwelling urethral catheter. Monitoring central venous pressure is advised to prevent overhydration. A sequential approach generally includes an initial slight overhydration by administration of a test dosage of polyionic solution IV at 50 mL/kg. If this fails to yield adequate urine flow within 3 hr, further measures include

osmotic diuresis (10% or 20% mannitol or dextrose, 0.5–1 g/kg, IV, as a slow bolus throughout 15–30 min, alternated with infusion of lactated Ringer's solution, 30 mL/kg, IV, throughout 30 min). Subsequent measures generally include furosemide (2 mg/kg, IV, which can be doubled and then tripled at 2-hr intervals if urine production does not increase above the target of 0.5 mL/kg/hr). However, furosemide may worsen the severity of AKI caused by aminoglycosides. Finally, renal vasodilators (dopamine diluted in 5% dextrose, IV, to provide 1–5 mcg/kg/min) plus furosemide (2 mg/kg, IV) may be tried for 2 hr. Dopamine may lead to ventricular arrhythmias, and high doses of dopamine may cause renal vasoconstriction. Dopamine produces minimal renal vasodilation in cats and calcium channel blockade (eg, amlodipine besylate, 0.25–0.5 mg/kg, or diltiazem, 1–3 mg/kg) may be preferred. If attempts to restore urine flow fail, aggressive measures should be discontinued to avoid overhydration. Daily fluid therapy based on maintenance and rehydration needs is continued until renal function and clinical condition improve. Feeding tube placement greatly facilitates patient management at this stage and should be implemented for any animal with marked renal azotemia (serum creatinine >10 mg/dL after rehydration).

A second therapeutic option, rather than the aggressive measures discussed above, is to proceed directly to fluid therapy with polyionic solutions while waiting for renal regeneration. Again, feeding tube placement for parenteral nutrition should be implemented in anorectic animals with marked azotemia. Peritoneal dialysis or hemodialysis may be necessary if none of the above measures restores urine production.

GLOMERULAR DISEASE

Glomerular disease is a well-recognized cause of chronic kidney disease (CKD) in dogs, may produce acute kidney injury in dogs, and is also occasionally seen in cats with CKD. These animals should be staged and substaged as recommended above (see TABLE 2, TABLE 3, and TABLE 4). Animals with primary glomerular disease as a cause of CKD may have somewhat different clinical and laboratory abnormalities than those with primary tubulointerstitial disease. Although uncommon, urine specific gravity may be inappropriately high for the degree of renal dysfunction, a condition referred to as glomerulotubular imbalance. Damage to the glomerular

basement membrane results in albuminuria, which may lead to hypoalbuminemia. Animals may then exhibit signs related to hypoalbuminemia (eg, peripheral edema, hypercoagulability with thrombosis, hypercholesterolemia) instead of or in addition to uremia.

Secondary glomerulopathies, observed as sequelae of systemic or glomerular hypertension in animals with Stage 3 or 4 CKD, are common. Although the overall prevalence of a primary glomerulopathy as an inciting cause is not known, it is apparently more common in dogs than cats.

Immune-mediated glomerulonephropathy is characterized by deposition or in situ formation of immune complexes in the glomerular capillary wall, which then incite inflammatory changes (see p 828). In one study of dogs, the mean age of presentation for glomerulonephritis was 4–8 yr; 55% were males, and there was no breed predilection. Immune-mediated glomerulonephritis has been associated with neoplasia, rickettsial diseases, systemic lupus erythematosus (SLE), heartworm disease, pyometra, chronic septicemia, and adenovirus infection, but it is usually idiopathic. Although multifactorial in origin, the glomerular disease associated with hyperadrenocorticism and diabetes mellitus in dogs is rarely attributable to immune complex formation.

In one study of cats with glomerulonephritis, the mean age at presentation was 3–4 yr; 75% were males, and there was no breed predisposition. Primary glomerular disease in cats is most frequently associated with chronic infection by feline leukemia virus (FeLV), feline immunodeficiency virus (FIV), or feline infectious peritonitis (FIP) virus but has also been reported in association with neoplasia and systemic inflammatory diseases. The relatively young age and predilection for males reflects the high prevalence of FeLV infection as a cause in reported feline cases.

Familial glomerulopathies as a primary cause of CKD have been reported in several breeds of dogs, including Bernese Mountain Dogs, English Cocker Spaniels, English Springer Spaniels, Doberman Pinschers, Greyhounds, Lhasa Apsos, Poodles, Rottweilers, Samoyeds, Shih Tzus, and Soft-coated Wheaten Terriers. These are not immune complex diseases, although some are characterized by proteinuria and associated clinical abnormalities that resemble those caused by immune-mediated glomerulonephropathy. Several of these breeds of dogs have genetic defects in collagen structure and function (types III or IV), analogous to hereditary nephropathies in

people such as Alport syndrome (hereditary nephritis).

Most cases of amyloidosis (see p 592) in dogs and cats, including familial amyloidosis in Chinese SharPei and Abyssinian cats, are reactive, or secondary, amyloidosis. In this form of the disease, amyloid A protein is deposited in various tissues after serum levels increase as a result of chronic inflammation. When the kidneys are affected, amyloid deposition in the nonfamilial forms in dogs usually occurs in the glomerulus. However, in Shar-Pei, at least 25% of Abyssinian cats, and in many domestic cats with the nonfamilial form of this disease, amyloid is found primarily in the medullary interstitium, where it interferes with the renal concentrating mechanism and is more likely to produce nonproteinuric CKD than protein-losing glomerular amyloid deposition. In contrast, glomerular amyloidosis usually leads to marked proteinuria. The nonfamilial form of amyloidosis usually affects middle-aged to older dogs and cats. Beagles, Collies, and Walker Hounds are reported to be at increased risk. Animals with the familial form of the disease are usually diagnosed at a younger age.

Clinical Findings: Glomerulopathy often leads to proteinuria (primarily albuminuria) and can produce hypoproteinemia, ascites, dyspnea (due to pleural effusion or pulmonary edema), and/or peripheral edema, which may be referred to as the nephrotic syndrome. Protein wasting can produce preferential loss of lean body mass that may be apparent on careful physical examination. Severe or chronic glomerular disease is a cause of CKD; most dogs and many cats with glomerular disease eventually develop Stage III or IV disease. Systemic hypertension may be more prevalent in proteinuric CKD and may be seen at any stage.

Proteinuria may result in loss of antithrombin III through the glomerular basement membrane, leading to a hypercoagulable state in dogs. Proteinuria also contributes to mild thrombocytosis and platelet hypersensitivity, which contribute to coagulation abnormalities in affected dogs, generally when plasma albumin levels are ≤ 1 g/dL. Severe dyspnea secondary to pulmonary thromboembolism or other sequelae of thrombotic disease may be seen in dogs with glomerulonephritis or amyloidosis. It is unclear whether a hypercoagulable state also exists in proteinuric cats, because clinical signs from hypercoagulability have not been reported in cats.

Diagnosis: The BUN, creatinine, and phosphorus concentrations are usually increased, although the degree varies with the stage of CKD at the time of diagnosis. Animals should be staged and substaged on the basis of measurements of blood pressure (see TABLE 3), proteinuria (see TABLE 4), and serum creatinine (see TABLE 2). Marked proteinuria with edema may be seen in the presence or absence of azotemia. Physical findings are usually nonspecific except that ascites, pleural effusion, and/or peripheral, pitting, nonpainful, subcutaneous edema are evident in some animals (75% of cats and 15% of dogs). Although uncommon, urine specific gravity may be inappropriately high for the degree of renal dysfunction. A urine protein:creatinine ratio >2 suggests a glomerular origin. If the sediment examination eliminates inflammatory urinary tract disease and hemorrhage as the source of proteinuria, then the degree of increase may help distinguish tubular proteinuria (typical ratio value of 0.5–2), glomerulonephritis (typical ratio value of 0.5–15), and glomerular amyloidosis (typical ratio value of 0.5–40). However, substantial overlap exists in these ranges, and a variety of glomerulopathies such as focal segmental glomerulosclerosis in dogs have yet to be well characterized. Further, the ratio tends to be low in the initial stages of a glomerulopathy, increases in severity as the disease progresses, and then decreases terminally as GFR falls to very low levels in late Stage 4 disease.

Renal biopsy is required to determine the type of glomerular disease. Membranous glomerulonephritis is reported most frequently in cats; there is a roughly equal distribution of histologic findings in dogs, with glomerular amyloidosis; focal segmental glomerulosclerosis; and membranous, proliferative, and membranoproliferative glomerulonephritis all represented. The degree of proteinuria does not always correlate with the severity of the histologic lesions or the degree of azotemia. Systemic hypertension develops in an unusually large proportion of animals with protein-losing glomerulonephritis; therefore, blood pressure should be determined in all animals with evidence of glomerular disease.

A careful search should be made for an inciting disease process. Abdominal and thoracic radiographs, ultrasonography, and specialized serologic tests can exclude various inflammatory, infectious, and neoplastic diseases. In dogs with glomerulonephritis, this includes tests for SLE (eg, antinuclear antibody titer and LE prep) and appropriate antigen or antibody screening tests for other infectious agents and

heartworm disease; in cats, tests for infection with FeLV, FIV, FIP, SLE, and heartworm disease should be included.

Treatment: There are six basic principles for treatment of glomerulonephropathies: 1) If a cause of immune complex disease can be identified, it should be treated. 2) Manifestations of the nephrotic syndrome, if present, should initially be managed by therapies designed to reduce proteinuria. This includes a renal diet low in protein and salt and subsequently, if needed, judicious use of diuretics. 3) Antithrombotics (eg, aspirin) should be considered for hypoalbuminemic (plasma albumin <1 g/dL) dogs but not cats, as well as for dogs with low serum levels of antithrombin III ($<30\%$ of normal). In dogs with marked proteinuria and serum albumin <2 g/dL, low-dose aspirin therapy (2.5–5 mg/kg/day, PO) is appropriate, unless melena is present or gastric ulceration is suspected. However, aspirin is bound to plasma proteins and is eliminated via the kidneys, so the lower end of the dosage range should be used in hypoalbuminemic dogs. 4) Because proteinuria may promote interstitial fibrosis, treatment to limit glomerular loss of protein is warranted and may include dietary protein restriction, n-3 polyunsaturated fatty acid supplementation, and administration of an angiotensin-receptor blocker (eg, telmisartan 1 mg/kg/day, PO) or angiotensin-converting enzyme inhibitor (eg, benazepril or enalapril, 0.5 mg/kg, PO, once daily in cats and bid in dogs). 5) Efforts to reduce the magnitude and consequences of glomerular immune complex deposition should be considered, especially in animals with biopsy-confirmed glomerular inflammation and no known primary antigenic stimulus. Immunosuppressive drugs (eg, mycophenolate, azathioprine, cyclophosphamide, cyclosporine) can be used in dogs with glomerulonephritis, although results are variable. For amyloidosis, dimethylsulfoxide and colchicine have been tried, without consistent results. These anti-inflammatory drugs should be administered only on a trial basis with owner consent. Corticosteroids seem to be beneficial only in mild glomerulopathy; they may worsen proteinuria in other glomerulopathies and should be avoided in animals with amyloidosis, because they are reported to enhance amyloid deposition. 6) Manifestations of CKD should be monitored and managed in accordance with the stage of disease (see p 1512).

Prognosis: Although one study found that mean survival time of dogs with glomerulo-

nephritis was 87 days, the prognosis with early diagnosis and appropriate therapy is much better. In a recent study of dogs with glomerulonephritis, those receiving a placebo medication survived beyond the entire 6-mo duration of the study. The prognosis for animals with amyloidosis is guarded but variable, with reported mean survival times ranging from 49 days to 20 mo.

RENAL TUBULAR DEFECTS

Renal Acidosis

The form of metabolic acidosis that occurs in acute kidney injury and Stages 2–4 of chronic kidney disease, referred to as uremic acidosis, is due to reduced urine-acidifying ability of diseased kidneys. In uremic acidosis, although the ability of individual tubular cells to reabsorb bicarbonate and/or secrete hydrogen ions may be normal, there is generally far less total cell mass present. Acid accumulates if the animal is under metabolic or dietary acid pressure, which is common in carnivores. This is particularly problematic in cats, which are often fed acidifying maintenance diets.

Rare renal tubular defects in dogs and cats may result in hyperchloremic metabolic acidosis, referred to as **renal tubular acidosis**. Two types of renal tubular acidosis have been described in dogs and one in cats. In Type I (distal), the ability of the distal tubule to secrete hydrogen ions against a concentration gradient is defective; in Type II (proximal), the ability to reabsorb bicarbonate in the proximal tubule is reduced. Type I has been reported in both species; Type II has also been described in dogs in conjunction with other proximal tubular defects in acquired (gentamicin nephrotoxicosis and an idiopathic form) and heritable (Fanconi syndrome, *see p 1520*) forms.

Type I renal tubular acidosis has been associated with demineralization of the skeleton (due to buffering of excess hydrogen ions) and nephrolithiasis (due to hypercalciuria from bone resorption) in dogs. Diagnosis is based on the presence of hyperchloremic metabolic acidosis with a urinary pH that is inappropriately high for the degree of systemic acidosis in the absence of bacterial urease modification of urine. Failure to produce acid urine in the face of metabolic acidosis or after oral ammonium chloride loading is diagnostic; however, this challenge test is contraindicated in animals that are already severely acidotic. Type II renal tubular acidosis is

diagnosed by demonstrating increased urinary fractional excretion of bicarbonate when plasma bicarbonate levels are normal or decreased; this test is not practicable in the clinical setting and diagnosis is presumptively based on history, signalment, and clinical pathology findings.

Therapy consists of oral administration of an alkalinizing agent sufficient to maintain normal blood pH (1 mEq bicarbonate equivalent/kg/day for Type I and 1–6 mEq bicarbonate equivalent/kg/day for Type II, PO). Therapy is more problematic in dogs with Type II renal tubular acidosis, because supplemental bicarbonate is readily lost in the urine.

Fanconi Syndrome

Fanconi syndrome is a generalized proximal tubular reabsorptive defect resulting in excessive loss of many solutes in the urine. It has been reported as an acquired condition in dogs (chicken jerky treat ingestion, gentamicin nephrotoxicosis, and an idiopathic form) and in a heritable form in a variety of breeds (most notably Basenjis), in which it develops gradually in adults of both sexes. There is excessive urinary loss of glucose, sodium, potassium, phosphorus, uric acid, bicarbonate, albumin, and amino acids. Blood glucose concentrations are normal. Serum electrolytes are normal early in the disease, but hypophosphatemia, hypokalemia, and metabolic acidosis are seen in the later stages.

Clinical signs include polydipsia, polyuria, and weight loss. Signs of uremia may be present if the animal is in Stage III or IV chronic kidney disease. Diagnosis is based on documentation of increased urinary fractional excretion of glucose, sodium, potassium, phosphorus, and bicarbonate in the presence of normal plasma concentrations. Hypoalbuminuria is likely to be present, because the proximal tubule normally reabsorbs the small amount of albumin that traverses the glomerular filtration barrier. Differential diagnoses include simple renal glucosuria and chronic kidney disease from other causes. The microscopic renal changes in the heritable form are not remarkable in the early stages but progress to nonspecific findings characteristic of chronic kidney disease. A genetic marker has been developed. A treatment regimen to reverse the tubular defect has not been described. The histologic appearance of the acquired forms of Fanconi syndrome vary, depending on the cause.

Oral supplementation of sodium chloride (5–10 mg/kg/day, PO), potassium (potassium citrate 10–30 mg/kg/day, PO), and alkali (sodium bicarbonate 10–30 mg/kg/day, PO) is indicated if the corresponding serum concentration is low. Dogs with acute or chronic kidney disease should be treated symptomatically as appropriate. The heritable disease is slowly progressive despite therapy and usually results in death from uremia.

Renal Glucosuria

This is usually a congenital defect in proximal tubular handling of glucose that results in glucosuria despite normal blood glucose concentration. Affected animals may be asymptomatic, have polydipsia and polyuria, or have recurrent or severe urinary tract infections due to bacterial colonization in the presence of glucose. Diagnosis is made by demonstrating persistent glucosuria despite a normal blood glucose concentration and by identifying no other renal reabsorptive abnormalities. This disease is so uncommonly recognized that little is known about its biologic behavior. The general consensus is that it is not progressive and does not require treatment, except that some animals with heritable Fanconi syndrome may initially exhibit glucosuria as the only clinically apparent renal reabsorptive defect.

OBSTRUCTIVE UROPATHY

Even though the kidneys would otherwise be able to function normally, obstruction of urine flow at any point below the level of the kidneys leads to accumulation of metabolic wastes and postrenal azotemia/uremia. Obstruction of the urethra by uroliths in dogs and by matrix-crystalline plugs in young male cats and obstruction of a ureter by a urolith in geriatric cats are the three most common causes, although uroliths, tumors, or blood clots may obstruct the ureters (or urethra) in either species.

Hydronephrosis is characterized by dilatation of the renal pelvis as the result of partial or complete obstruction of outflow of urine from one or both kidneys. When the obstruction is acute, complete, and bilateral, morphologic changes in the kidneys are less extensive, because the period of survival is short. In unilateral or partial obstruction, the animal often survives long enough for severe pressure atrophy of the renal parenchyma and cystic enlargement of the affected kidney to

develop. Hydroureter commonly develops when the obstruction is located lower in the tract. Increased hydrostatic pressure results in atrophy of functional renal parenchyma. The pseudodiverticula of the renal pelvis disappear first; later, even the cortex may atrophy. The affected kidneys eventually become grossly enlarged, functionless sacs, filled with urine or serous fluid that may harbor bacteria.

Clinical Findings: Animals with urethral obstruction frequently exhibit pollakiuria, stranguria, and hematuria; abdominal pain may be marked. Signs of uremia develop rapidly and include vomiting, dehydration, hypothermia, and severe depression. The bladder is distended and painful on palpation, and a urethral catheter cannot be readily passed. Bradycardia or cardiac arrhythmias due to hyperkalemia may be present, particularly if plasma potassium is >7 mEq/L. Because compensatory hypertrophy of the nonaffected kidney results in a nonazotemic state, unilateral ureteral obstruction commonly is undiagnosed, unless the animal has accompanying renal disease or the enlarged, hydronephrotic kidney is palpated during physical examination and/or seen on radiologic or ultrasonographic imaging studies.

Diagnosis: The history, clinical signs, and physical examination usually provide a straightforward diagnosis of urethral obstruction. Ureteral obstruction should be suspected in any acutely uremic cat, including those with a history of chronic kidney disease. Excretory urography or abdominal ultrasonography are necessary to establish a diagnosis in animals with bilateral or unilateral ureteral obstruction. Serum potassium levels should be determined immediately in animals with cardiac arrhythmias. An ECG can provide presumptive evidence of hyperkalemia (bradycardia; tall, peaked T waves; increased PR interval; widened QRS complex; atrial standstill) if laboratory results are delayed.

Treatment: The urethral obstruction should be relieved (*see* p 1525). Fluids given IV improve renal function and correct electrolyte and acid-base abnormalities. Normal saline is preferred but not required in hyperkalemic animals. Unless the animal is markedly hyperkalemic (serum potassium >7 mEq/L), has cardiac arrhythmias, or is known to have preexisting kidney disease, it is often best to avoid overcorrection by allowing plasma potassium and acid-base

balance to return toward normal via restoration of renal excretory function for 12 hr before administering therapy specifically intended to correct these abnormalities. In animals with severe hyperkalemia and cardiac arrhythmias, bicarbonate (0.5 mEq/kg, given slowly IV over 5 min) or regular insulin and dextrose infusions can be given to drive potassium intracellularly. Because of a postobstructive diuresis that lasts for 1–5 days, hypokalemia and/or dehydration are often seen within 24–48 hr after correction of urethral obstruction. Plasma electrolytes, body weight, urine output, hematocrit, and plasma total solids should be monitored daily, with the type and quantity of fluid administered adjusted appropriately.

Surgery is often necessary to correct complete ureteral obstruction. When possible, the obstruction should be removed to reestablish urine flow. In some cases, ureteroliths will pass through the ureters, eliminating the need for surgery. This may require partial ureteral resection and reimplantation, particularly in cats, which have very small and friable ureters. In some cases, unilateral nephrectomy may be required, but a kidney should not be removed without clear evidence that the contralateral kidney is capable of sustaining life. Preferred evidence includes the estimation of GFR in the contralateral kidney but could alternatively be based on the following criteria: normal renal size, shape, and consistency on ultrasonography; presence of normal vascular and excretory phases on excretory urography; normal renal ultrasonographic examination; and normal renal biopsy.

NEOPLASIA

Neoplasms of the Kidney

Neoplasms of the kidney are uncommon and represent ~0.5%–1.7% of all neoplasms in dogs. Benign neoplasms are uncommon, usually incidental findings at necropsy, and generally of little clinical significance. Adenomas, lipomas, fibromas, and papillomas have been reported.

Primary malignant renal neoplasms (except nephroblastomas) are most common in middle-aged to older animals. No breed predilection has been found, except for heritable predilection for the development of bilateral, multifocal cystadenocarcinomas in German Shepherds, generally between 5–11 yr of age. The most common primary malignant renal neoplasm is carcinoma, which originates from the renal tubular epithelium. Usually, it is unilateral,

located at one pole of the kidney, and well demarcated. Size varies from microscopic to several times that of the normal kidney, and color may be yellow, white, or gray. Renal carcinomas metastasize early to various organs; the opposite kidney, lungs, liver, and adrenals are involved most commonly.

Nephroblastomas (embryonal nephroma, Wilms' tumor) arise from vestigial embryonic tissue. They are seen in young animals and, in dogs, are most commonly diagnosed at <1 yr of age. There is no breed predilection. Males are affected twice as commonly as females. Nephroblastomas are usually unilateral but are occasionally bilateral. They can grow to immense size; it is not uncommon to have virtually the entire abdomen occupied by tumor. Metastasis may occur to regional lymph nodes, liver, and lungs.

Transitional cell carcinomas arise from transitional epithelium of the renal pelvis, ureter, bladder, or urethra (*see* p 1523). Other primary malignant renal neoplasms are uncommon and include hemangiosarcomas, fibrosarcomas, leiomyosarcomas, and squamous cell carcinomas.

The kidneys are a common site of metastatic or multicentric neoplasms. Metastatic lesions may be unilateral or bilateral. Lymphosarcoma is the most common multicentric tumor involving the kidneys. As many as 50% of dogs and cats with lymphosarcoma have renal lesions and, in some cases, only the kidneys or kidneys and brain are affected. Renal involvement is usually multifocal or diffuse, interstitial, and bilateral, and results in large, irregular kidneys. Lymphosarcoma in cats frequently is associated with infection by feline leukemia virus.

Clinical Findings: Signs are nonspecific and may include weight loss, anorexia, depression, and fever. Bilateral neoplasms may uncommonly destroy sufficient renal tissue to cause chronic kidney disease and associated signs of uremia. Astute owners may notice "lumps" in their animal's abdomen or abdominal enlargement. Persistent hematuria, usually microscopic, may occur. Rarely, renal tumors may produce excessive erythropoietin, which results in erythrocythemia (*see* p 43).

Diagnosis: History and clinical signs may indicate a mass in the area of the kidneys or renomegaly, which can be confirmed by ultrasonography or radiography, although an excretory urogram or renal arteriogram may be required. Radiographs of the thorax may reveal metastatic disease. Neoplastic cells occasionally can be found in the urine

sediment. A tissue sample suitable for a diagnosis may be obtained via catheterization. Cystoscopic biopsy can be an effective method to obtain a diagnostic sample in dogs with transitional cell carcinoma of the bladder and urethra, especially females. Percutaneous needle aspiration and cytologic examination may be sufficient for the diagnosis of lymphosarcoma in cats and dogs, particularly when there is diffuse involvement or with ultrasonographic guidance when multifocal disease occurs. Histologic examination of tissue obtained by cystoscopy, needle biopsy, or surgical wedge biopsy is often necessary to determine the type of tumor.

Treatment: Ultrasound-guided endoscopic diode laser ablation holds promise as a palliative treatment for dogs with transitional cell carcinoma of the urinary tract. Otherwise, treatment of all renal neoplasms except lymphosarcoma involves surgical removal; unilateral nephrectomy is usually required. Lymphosarcoma is best managed by combination chemotherapy (see p 40). Chemotherapy is generally ineffective against renal tumors other than lymphosarcoma.

Neoplasms of the Lower Urinary Tract

Neoplasms of the ureters, bladder, and urethra are uncommon in dogs and rare in cats. The low incidence in cats may be due to a difference in tryptophan metabolism that results in low urinary concentrations of carcinogenic tryptophan metabolites. The mean age of affected dogs and cats is 9 yr.

In the lower urinary tract, primary neoplasms are more likely to be malignant than benign. Papillomas, leiomyomas, fibromas, neurofibromas, hemangiomas, rhabdomyomas, and myxomas are found infrequently.

Among primary malignant neoplasms of the lower urinary tract, transitional cell carcinomas are diagnosed most frequently in both species. Squamous cell carcinomas, adenocarcinomas, fibrosarcomas, leiomyosarcomas, rhabdomyosarcomas, hemangiosarcomas, and osteosarcomas also are found. Transitional cell carcinomas may be solitary or multiple papillary-like projections from the mucosa or may develop as a diffuse infiltration of the ureter, bladder, prostate, and/or urethra. Cystic transitional cell tumors are more common in certain breeds of dogs, particularly Scottish Terriers, have been associated with prior therapy with cyclophosphamide, and

may be linked to exposure to herbicides and older-generation insecticides. Transitional cell tumors are highly invasive and metastasize frequently, most commonly to the regional lymph nodes and lungs. Ureteral and bladder neoplasms can cause chronic obstruction to urine flow with secondary hydronephrosis. Urethral tumors are more likely to cause acute obstructive uropathy. Intractable secondary bacterial urinary tract infections are commonly associated with neoplasms of the bladder and urethra.

Clinical Findings: Hematuria, dysuria, stranguria, and pollakiuria are the most common signs. Animals with ureteral obstruction and unilateral hydronephrosis may show signs of abdominal pain and have a palpable, enlarged kidney. Signs of uremia may be apparent in animals with bilateral ureteral obstruction and hydronephrosis or with urethral obstruction. The bladder wall may be thickened, and a cord-like urethra or urethral mass(es) may be palpable rectally.

Diagnosis: History and clinical signs are highly suggestive of lower urinary tract disease in animals with tumors of the bladder or urethra. Urinalysis frequently reveals hematuria, and there may be evidence of secondary infection. Chronic, uncomplicated urinary tract infections must be differentiated from those associated with neoplasms. Neoplastic cells may be found in the sediment, particularly with transitional cell carcinomas. For bladder tumors in dogs, the veterinary bladder tumor antigen test may be helpful, although false-positives do occur. A cystourethrogram, retrograde urethrogram, or ultrasonography is generally necessary to determine the location and

extent of the tumor. Biopsy of the tumor is required for definitive diagnosis.

Treatment: Excision of the tumor, if possible, is the most beneficial therapy. Transitional cell carcinomas are frequently located at the trigone of the bladder or in the urethra and may necessitate radical reconstructive surgery of the lower urinary tract. Prognosis is poor for these animals, even with surgery, because recurrence and metastasis occur rapidly. Radiation therapy and/or chemotherapy with piroxicam, cisplatin, doxorubicin, vinblastine, chlorambucil, or mitoxantrone will generally prolong the life of affected animals. Dogs with transitional cell carcinoma, including those being treated for the tumor, are predisposed to development of bacterial urinary tract infections, and routine urine cultures are indicated.

DISORDERS OF MICTURITION

Disorders of micturition result from a dysfunction in the storage or voiding of urine and may be neurogenic or non-neurogenic in origin. Urinary incontinence is the failure of voluntary control of micturition, with constant or intermittent unconscious passage of urine. Incontinent animals may leave a pool of urine where they have been lying or may dribble urine while walking. The coat around the vulva or prepuce may be wet, and perivulvar or peripreputal dermatitis can result from urine scalding.

Failure of urine storage is characterized by inappropriate leakage of urine due to failure of bladder relaxation, urethral incompetence, anatomic defects, or overflow of stored urine. Urge incontinence is seen with detrusor irritability, usually associated with cystitis. The most common non-neurogenic incontinence is attributed

to deficiency of sex hormones in neutered animals, particularly female dogs, and is referred to as hormonal-responsive urethral incompetence. Idiopathic urethral sphincter incompetence also is seen. Urinary incontinence associated with anatomic defects may be detected in animals at an early age. For example, an animal with a unilateral congenital ectopic ureter may void normally but “dribble” urine intermittently, whereas animals with bilateral ectopic ureters are less likely to void normally. Paradoxical urinary incontinence may develop when there is a partial obstruction of the urethra leading to bladder distention and overflow incontinence.

Failure of normal voiding is characterized by frequent attempts to urinate with stranguria and passage of only small amounts of urine. Inability to urinate can be due to mechanical obstruction of the urethra by calculi, neoplasms, or strictures; detrusor atony from overdistention of the bladder; or neurologic disease. Animals with abnormalities of the voiding phase may develop overflow incontinence due to dribbling of urine associated with bladder overdistention.

Neurologic causes of micturition disorders can be categorized as upper (UMN) or lower motor neuron (LMN) lesions. Lesions in the sacral spinal cord, pelvic nerve, and detrusor atony lead to LMN signs, which are often characterized by a distended, easily expressed bladder. Dysautonomia in cats is a multisystemic disease characterized by widespread disruption of autonomic system functions, including urinary incontinence of LMN origin. Damage to the thoracolumbar spinal cord or disease of the cerebrum, cerebellum, or brain stem can lead to UMN signs, characterized by a distended bladder that is difficult to express. Another neurologic cause of inability to urinate is functional obstruction (detrusor-sphincter reflex dyssynergia), which occurs when there is incoordination of the normal micturition reflex; this is believed to result from overdischarge of sympathetic nerve impulses to the urethral sphincter, resulting in a failure of urethral relaxation during detrusor contraction. Animals with neurogenic incontinence may leak urine (LMN) and/or develop overflow incontinence due to dribbling of urine associated with bladder overdistention (any neurogenic cause).

Diagnosis: Clinical signs are usually suggestive of a micturition disorder. The his-

tory should include age of onset, whether the animal is intact or neutered, age at neutering, current medication, and history of previous urinary tract disorders. A thorough physical and neurologic examination is indicated, and the act of voiding should be observed, including estimation of initial and final bladder volume.

Animals with LMN lesions or an atonic bladder have a large, distended bladder that can be expressed with minimal pressure. Animals with mechanical or functional obstruction or with spinal lesions causing UMN signs also have a large distended bladder, but urine cannot be readily expressed. Caution must be exercised when attempting to express urine from these animals to avoid rupturing the bladder. Plain or contrast radiography, cystoscopy, or ultrasonography are necessary to determine the type and location of mechanical obstruction.

Animals with functional obstruction (reflex dyssynergia) generally exhibit pollakiuria with interrupted urine stream, distended urinary bladder, no identifiable structural cause of obstruction, and overflow incontinence; the neurologic examination is generally abnormal. A catheter can easily be passed into the bladder in animals with functional obstruction but will not pass in animals with mechanical obstruction.

Treatment: Accurate diagnosis or localization of the lesion is essential for appropriate pharmacologic management. Animals with hormonal incontinence can be treated with the appropriate sex hormone (eg, diethylstilbestrol in females and testosterone in males). The dosage should be adjusted to the minimum required to maintain continence. Diethylstilbestrol may be difficult to obtain. Alternatively, an α -adrenergic agonist drug (eg, phenylpropanolamine, 2–4 mg/kg/day in divided doses) can be given to animals with urethral incompetence alone or in combination with an estrogenic compound. Although ephedrine is another α -agonist shown to be effective in the treatment of urinary incontinence in female dogs, its use is more often associated with adverse effects of anxiety and excitability. Pseudoephedrine is apparently not effective for this purpose. Urge incontinence (detrusor instability) is treated with anticholinergic drugs such as oxybutin chloride (0.5 mg/kg/day, PO) or propantheline (dogs <20 kg, 7.5 mg/day; dogs >20 kg, 15 mg/day; cats, 7.5 mg every 72 hr). Cholinergic drugs such as bethanechol are used in animals with detrusor

atony. Functional obstruction is treated with sympatholytic drugs (eg, phenoxybenzamine, 2.5–10 mg, 1–3 times/day); cholinergic drugs may also be necessary.

Complete mechanical obstruction of the urethra is a medical emergency and should be relieved by catheterization and retropulsion of the obstructing material into the bladder or by surgery. Animals with detrusor atony from overdistention but without neurologic lesions benefit from decompression of the bladder by placement of an indwelling urinary catheter for 3–7 days. This may be done continuously or intermittently. Those with neurogenic atony, which usually does not respond to medical management, may require manual expression of the bladder or catheterization several times daily.

UROLITHIASIS

Some mineral solutes precipitate to form crystals in urine; these crystals may aggregate and grow to macroscopic size, at which time they are known as **uroliths** (calculi or stones). Uroliths generally contain an organic matrix that is believed to vary minimally among uroliths and that constitutes ~2%–10% of the stone's chemical composition. The remaining 90%–98% of the urolith is composed of minerals that vary depending on the type of urolith. **Urolithiasis** is a general term referring to stones located anywhere within the urinary tract. Uroliths can develop in the kidney, ureter, bladder, or urethra and are referred to as nephroliths, ureteroliths, urocystoliths, and urethroliths, respectively.

Uroliths in all animal species are composed of ~10 different minerals. Identification of the minerals in uroliths by qualitative analysis is unreliable. The type of minerals in uroliths can be readily identified by optical crystallography, infrared spectroscopy, and/or x-ray diffraction. Minerals found in uroliths have a chemical name and often a mineral or crystal name (see TABLE 5). Variation in urine characteristics over time can result in more than one crystal type within a single urolith. In such instances, the urolith core corresponds to conditions that were present when the urolith initially formed, and the outer layers correspond to more recent conditions.

Mechanisms involved in stone formation are incompletely understood in dogs and cats. However, three main contributing factors are 1) matrix—the inorganic protein core may facilitate initial urolith formation, 2) crystallization inhibitors—organic and inorganic crystallization inhibitors may be

TABLE 5 UROLITH NAMES

Mineral Name	Chemical Formula	Chemical Name
Struvite	$\text{MgNH}_4\text{PO}_4 \cdot 6\text{H}_2\text{O}$	Magnesium ammonium phosphate hexahydrate
Whewellite	$\text{CaC}_2\text{O}_4 \cdot \text{H}_2\text{O}$	Calcium oxalate monohydrate
Weddellite	$\text{CaC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$	Calcium oxalate dihydrate
Hydroxyapatite	$\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$	Calcium phosphate (hydroxyl form)
Urate	$\text{C}_5\text{H}_4\text{N}_4\text{O}_3$	Urate
Ammonium urate	$\text{NH}_4 \cdot \text{C}_5\text{H}_4\text{N}_4\text{O}_3$	Ammonium urate
Sodium urate	$\text{Na} \cdot \text{C}_5\text{H}_4\text{N}_4\text{O}_3 \times \text{H}_2\text{O}$	Sodium urate monohydrate
Cystine	$(\text{SCH}_2\text{CHNH}_2\text{COOH})_2$	Cystine
Silica	SiO_2	Silica
Xanthine	$\text{C}_8\text{H}_4\text{N}_4\text{O}_2$	Xanthine

lacking or dysfunctional in animals with uroliths, and 3) precipitation crystallization factors—a complex relationship among urine solutes and other chemical factors in the urine can lead to conditions favoring crystallization. Regardless of the underlying mechanism(s), uroliths are not produced unless sufficiently high urine concentrations of urolith-forming constituents exist and transit time of crystals within the urinary tract is prolonged. For selected stones (eg, struvite, cystine, urate), other favorable conditions (eg, proper pH) for crystallization must also exist. These criteria can be affected by urinary tract infection, diet, intestinal absorption, urine volume, frequency of urination, therapeutic agents, and genetics.

Clinical signs associated with urolithiasis are seldom caused by microscopic crystals. However, formation of macroscopic uroliths in the lower urinary tract that interfere with the flow of urine and/or irritate the mucosal surface often results in dysuria, hematuria, and stranguria. Nephroliths often are asymptomatic unless pyelonephritis exists concurrently or they pass into the ureter. Ureteral obstruction may produce signs of vomiting, lethargy, and/or flank and renal pain, particularly if there is acute total obstruction with distention of the renal capsule. The only clinical sign associated with unilateral urethroliths may be pain, which can be difficult to detect in dogs and cats. If these initial signs of ureteral obstruction do not lead to a diagnosis, unilateral ureteral obstruction may result in hydronephrosis with loss of function of the ipsilateral kidney. Ureteroliths may also precipitate

a uremic crisis in cats with previously compensated chronic renal failure. Because clinical signs of renal dysfunction are generally not apparent until two-thirds or more of total functional renal parenchyma is lost, clinical signs may not be seen except in the following situations: 1) both ureters are obstructed, 2) there is contralateral chronic kidney disease, or 3) a renal infection develops. Unilateral ureteroliths may be identified serendipitously during abdominal imaging studies or surgery.

Abdominal palpation can help detect urocystoliths; the bladder wall may be thickened, and a grating sensation may be felt when the bladder is palpated. Although palpation may reveal a single large urolith or multiple uroliths by their crepitation, it cannot dependably identify all animals with uroliths; urethral calculi may be detected by rectal palpation or located by passing a catheter. Because multiple uroliths may be present throughout the urinary tract, a complete radiographic examination of the tract is indicated; radiodense calculi >3 mm in diameter are usually visible on radiographs. Urate, and occasionally cystine, uroliths may be radiolucent, requiring contrast radiography or ultrasonography to confirm their presence. Urinalysis, including identification of crystals on microscopic examination of fresh, warm urine and bacterial culture and sensitivity testing, is a critical part of the evaluation and may help determine the type of urolith present. Ultrasonography and cystoscopy may also be useful.

Urethral Obstruction: Urethral obstruction is common in male dogs

and cats. It may occur suddenly or may develop throughout days or weeks. Initially, the animal may frequently attempt to urinate and produce only a fine stream, a few drops, or nothing. Animals may also exhibit extreme pain manifested by crying out when attempting to urinate. Complete obstruction causes uremia within 36–48 hr, which leads to depression, anorexia, vomiting, diarrhea, dehydration, coma, and death within ~72 hr. Urethral obstruction is an emergency condition, and treatment should begin immediately.

If the bladder is intact, it is distended, hard, and painful; care should be used when palpating the bladder to avoid iatrogenic rupture. If the bladder has ruptured, it cannot be palpated and urine can sometimes, but not always, be obtained from the abdominal cavity by paracentesis. Animals with spontaneous bladder rupture may appear temporarily improved because the pain associated with bladder distention has been relieved; however, peritonitis and absorption of uremic toxins and potassium occur rapidly and lead to depression, abdominal distention, cardiac arrhythmias, and death.

Hyperkalemia and metabolic acidosis are life-threatening complications of urethral obstruction. An ECG (to record cardiac rhythm and rate) and a serum potassium are indicated. Initial emergency care involves immediate relief of obstruction by catheterization and fluid therapy with normal saline. Occasionally, an obstruction at the external urethral orifice can be dislodged by gentle massage. Sometimes, when a portion of the urethra is dilated with fluid under pressure and then suddenly released, urethral calculi can be flushed out. The urolith nearly always can be flushed back into the bladder by using the largest catheter that can be easily passed to the calculus, occluding the distal end of the urethral lumen around the catheter, and infusing a sterile mixture of equal parts of isotonic saline solution and an aqueous lubricant. If the urethrolith cannot be flushed back into the bladder, a urethrotomy should be performed to remove the obstructing stone(s). Depending on the clinical circumstances, the urethrotomy site may be sutured or a permanent urethrostomy created. Calculi flushed back into the bladder should be removed by cystotomy to prevent recurrence, although in some cases they can be dissolved. The stone should be sent for quantitative analysis, with the animal managed medically to prevent stone recurrence based on the results.

Canine Urolithiasis

The most common canine uroliths are magnesium ammonium phosphate, calcium oxalate, or urate; less common uroliths include cystine, silica, calcium phosphate, and xanthine. While general management includes surgical removal and medical management, the appropriate treatment protocol depends on the location of the urolith and its chemical composition, as well as on patient-specific factors. Nephrolithiasis is generally not associated with an increase in the rate of progression of kidney injury; thus, it is recommended that animals with nephrolithiasis be managed without surgery in most cases.

Struvite Stones: The most common urinary stones in dogs are composed of struvite. The mineral composition is mostly struvite ($\text{MgNH}_4\text{PO}_4 \cdot 6\text{H}_2\text{O}$), but frequently, small amounts of carbonate-apatite and ammonium urate are present. In most cases, struvite uroliths form in association with urinary tract infections with urease-producing *Staphylococcus* or *Proteus* spp. Although they are frequent in cats, sterile struvite uroliths rarely form in dogs. They have been detected in a family of English Cocker Spaniels, suggesting a genetic predisposition.

Medical management involves dissolution and prevention of stone formation. In both instances, the aim of treatment is to reduce the concentrations of NH_4^+ , Mg^{2+} , and PO_4^{3-} in urine. For dissolution, urine should be extremely undersaturated for struvite; for prevention, the degree of struvite saturation should be sufficiently low to make crystallization unlikely. The choice between surgery, lithotripsy, and medical treatment may not be easy. Owner compliance, the animal's acceptance of the diet, availability of lithotripsy, practice philosophy, and knowledge of the indications and contraindications are necessary to make a decision. If stone dissolution is prolonged or fails, it may be more costly than surgical treatment. Surgical removal of uroliths is often incomplete, with small, hidden uroliths often inadvertently left in the urinary tract serving as a nidus for recurrence.

Before beginning stone dissolution by medical therapy, a physical examination, CBC, serum chemistry profile, urinalysis, urine culture and sensitivity, abdominal radiographs to document stone size, and blood pressure measurement (if possible) should be performed. Contraindications to stone dissolution include heart failure,

edema, ascites, pleural effusion, hypertension, hepatic failure, renal failure, and hypoalbuminemia. However, chronic kidney disease is not always a contraindication for dissolution of struvite nephroliths.

Dissolution Protocol: While the use of urinary acidification to reduce urine pH to <6 and other individualized dietary maneuvers may prove effective, a few commercially available diets that are generally nutritionally balanced promote struvite stone dissolution. Dogs fed these rations generally have reduced intake of protein, phosphate, and magnesium and a high intake of sodium. This results in osmotic diuresis, reduced daily urea output, and enhanced urine volume. The low urinary urea concentration is one of the most important features of such diets and also reduces ammonia production by the action of urease-producing bacteria. No other food, including treats, should be fed, and adequate fresh water should be available at all times.

Urease-producing urinary tract infections must be treated. The choice of antibacterial should be based on sensitivity testing when possible. Most *Staphylococcus* and *Proteus* infections are sensitive to levels of amoxicillin or ampicillin achieved in the urine of healthy dogs. A urease inhibitor can be given but is not usually necessary. Concurrent treatment with a urease inhibitor such as acetohydroxamic acid enhances the rate of struvite stone dissolution, particularly when antibiotic resistance precludes effective antibacterial sterilization of the urine. A reasonably safe dose of acetohydroxamic acid appears to be 12.5 mg/kg, PO, bid. A reversible, mild hemolytic anemia has been seen in dogs given higher dosages.

After ~4 wk of treatment, a physical examination, serum chemistry profile, urinalysis, and abdominal radiographs or ultrasonography should be repeated. The stone dissolution protocol should be discontinued if severe adverse effects develop, although a mild degree of hypoalbuminemia is to be expected and can be tolerated. With good compliance, the following results can be anticipated: urine pH <6.5, urine specific gravity <1.025, serum urea <10 mg/dL. The radiographic stone size should be compared with the size on previous radiographs. Routine testing should be repeated every 4 wk until 4 wk after the stone is no longer visible radiographically; this generally takes 8–12 wk but may take as long as 20 wk. Stones that fail to reduce in size after 8 wk of treatment are probably not composed of struvite and should be treated another way,

although failure could also result from poor treatment compliance. Renal stones tend to dissolve more slowly than bladder stones.

The recurrence rate after surgical treatment of struvite uroliths has been reported to be ~20%–25%, with most recurrences within 1 yr. When surgery is performed to remove multiple small struvite calculi, removing all stone material is often difficult. In such cases, a 4-wk dissolution protocol starting at the time of suture removal aids in preventing recurrence due to residual crystalline material. Once the urinary tract is free of stones, prevention strategies are much more likely to be successful.

Prevention Protocol: The key to prevention of recurrence in animals with a struvite stone associated with infection is to achieve and maintain sterile urine. Routine testing of urine pH by the owner is important. If fresh urine is alkaline, a urinalysis and culture should be done, with the dog treated appropriately if an infection is present.

Once stone dissolution is completed, a prevention program can be considered. The aim is to prevent urinary tract infections with urease-producing microbes. The concentration of major struvite solutes in urine should also be reduced. A commercially available diet may be fed to lower urinary phosphate and magnesium and to maintain an acidic urine. Urease-producing infections should be eliminated, after which owners should regularly check the pH of the first voided urine in the morning after an overnight fast; in most dogs on a normal diet, the urine will be acidic. Checking urine pH weekly is sufficient.

Calcium Oxalate Stones: Calcium oxalate uroliths have been increasing in frequency in dogs. Although they may develop in any breed, Miniature Schnauzers, Lhasa Apsos, Yorkshire Terriers, Bichon Frises, Shih Tzus, and Miniature Poodles may be predisposed. Most affected dogs are 2–10 yr old. Hypercalciuria leading to calcium oxalate stone formation can result from increased renal clearance of calcium due to excessive intestinal absorption of calcium (absorptive hypercalciuria), impaired renal conservation of calcium (renal leak hypercalciuria), or excessive skeletal mobilization of calcium (resorptive hypercalciuria).

Absorptive hypercalciuria is characterized by increased urine calcium excretion, normal serum calcium concentration, and normal or low serum parathormone concentration. Because absorptive

hypercalciuria depends on dietary calcium, the amount of calcium excreted in the urine during fasting is normal or significantly reduced when compared with nonfasting levels. Renal leak hypercalciuria has been recognized in dogs less frequently than absorptive hypercalciuria. In dogs, renal leak hypercalciuria is characterized by normal serum calcium concentration, increased urine calcium excretion, and increased serum parathormone concentration. During fasting, these dogs do not show a decline in urinary calcium loss. The underlying cause of renal leak hypercalciuria in dogs is not known. Resorptive hypercalciuria is characterized by excessive filtration and excretion of calcium in urine as a result of hypercalcemia. Hypercalcemic disorders have been associated only infrequently with calcium oxalate uroliths in dogs.

Routine laboratory determinations should include serum calcium, phosphate, total CO_2 , and chloride to eliminate the possibility of hyperparathyroidism and renal tubular acidosis. Dissolution of calcium oxalate stones by medical means has not currently been established. Treatment requires surgical removal or lithotripsy followed by preventive strategies.

Prevention Protocol: Recurrence is a major problem with calcium oxalate uroliths. An "ideal" diet is considered to be low oxalate, low protein, and low sodium and would maintain urine pH at 6.5–7.5 and urine specific gravity <1.020 . A few commercially available canned foods achieve these goals and may minimize the risk of recurrence. Potassium citrate may be added as needed to assure the urine pH is within the desired range; water may be used to provide appropriate reduction in urine concentration. If these urine conditions are achieved and calcium oxalate crystals are still seen in warm, fresh urine, then vitamin B_6 and/or thiazide diuretics can be considered (although of unproven efficacy). Effectiveness of therapy should be reevaluated at 1- to 4-mo intervals by urinalysis. Chlorothiazide diuretics may also be of value.

Urate Stones: Ammonium urate stones are most common in Dalmatians and in dogs with congenital portosystemic vascular shunts. The formation of ammonium urate calculi depends on the urine concentrations of urate and ammonium and on other poorly understood factors. Dalmatians do not convert most of their metabolic urate to allantoin and thus excrete the bulk of

nucleic acid metabolites as relatively insoluble urate. The biologic mechanism responsible for decreased hepatic conversion of urate to allantoin lies not in reduced uricase activity but in reduced hepatic transport of urate; the rate of urate hepatic transport is approximately three times faster in breeds other than Dalmatians. The net result is that only 30%–40% of urate is converted to allantoin in Dalmatians compared with ~90% in other breeds.

Dalmatians fed a diet high in animal protein excrete a net acid load in the urine, and urinary ammonium output is subsequently increased. The combined high concentration of ammonium and urate in urine increases the risk of formation of ammonium urate stones. The excretion of acidic metabolites of an animal protein diet is believed to be important in this process, because urinary ammonium excretion is enhanced and ammonium urate is insoluble. Urate output has been reported to be the same in Dalmatians that form stones and in those that do not, although in some studies the methods used to determine urine uric acid concentrations were unreliable. In dogs with a portosystemic vascular anastomosis, increased urinary ammonium output may partially be due to the increased filtered load of ammonia, because plasma levels of ammonia tend to be increased.

Dissolution Protocol: Urine alkalinization minimizes renal ammonia production; the goal is to achieve a urine pH >7 . If required, urine alkalinization can be achieved by administering NaHCO_3 , 1 g ($\frac{1}{4}$ tsp)/5 kg, PO, tid, with food. Potassium citrate, administered to effect (25–50 mg/kg/day) is an alternative, more palatable alkalinizing agent.

Urinary urate output should be reduced. This can be accomplished by feeding a low-purine, low-protein commercial diet. In addition, the xanthine oxidase inhibitor allopurinol (15 mg/kg, PO, bid) may be administered to ensure the nucleic acid metabolite load is excreted as a combination of xanthine, hypoxanthine, uric acid, and allantoin, rather than almost entirely as urate. However, the effectiveness of allopurinol in reducing urinary urate output is variable, and urinary urate levels should be measured (although this may be difficult). Allopurinol must be used cautiously in dogs with hepatic disease or primary renal failure, because it is metabolized to its active form in the liver and is excreted via the kidneys. It is important that diets high in purines not be fed to dogs receiving allopurinol because xanthine uroliths may result.

Urine volume should be increased to reduce the concentration of all dissolved solutes in urine. This can be achieved by feeding canned diets restricted in protein. By reducing formation of urea, renal medullary urea concentration declines, interfering with the countercurrent system of urine concentration. Adding salt, 1 g (¼ tsp)/5 kg, daily to the diet, or mixing water with the food are additional methods. Salt should not be given to animals with hypertension but otherwise poses little risk in normotensive dogs without chronic kidney disease, proteinuria, or hypoalbuminemia.

Prevention Protocol: Prevention strategies aim to reduce the concentration of ammonium and urate in urine to levels unlikely to induce flocculation.

A low-protein, low-purine diet should be fed to reduce urinary urate output. Alkalinization should be used as needed to ensure alkaluria. Treatment with allopurinol (10 mg/kg/day, PO) can be considered. Ideally, allopurinol is not needed as a supplement to dietary management; however, if urate crystals persist, a low-maintenance dose of allopurinol is appropriate.

These dissolution and prevention strategies were developed for use in Dalmatians in which hepatic conversion of urate to allantoin is reduced but the liver is otherwise normal. They may not be safe for use in dogs with portosystemic vascular shunts. Such dogs tend to develop hypoalbuminemia, edema, and ascites when fed a low-protein diet. The safety of allopurinol in these dogs has not been established. In addition, alkalinization can predispose to hepatic encephalopathy because of increased GI absorption of dietary protein metabolites.

Cystine Stones: Stones composed almost entirely of cystine form in dogs that have a renal tubular amino acid reabsorption defect known as cystinuria. Healthy dogs demonstrate 97% fractional reabsorption of cystine, whereas affected dogs excrete a much greater proportion of the filtered cystine load and may even exhibit net cystine secretion. Cystine is a relatively insoluble amino acid; therefore, in high concentration it may precipitate and form stones. Despite excessive urinary loss of cystine in cystinuric dogs, plasma cystine levels remain the same as in healthy dogs; in fact, the only morbidity or mortality associated with the inherited defect of cystine reabsorption is urolith formation. Identification of cystine crystals by urinalysis indicates the dog is at risk of forming cystine uroliths. For poorly

understood reasons, not all cystinuric dogs develop uroliths. However, the absence of uroliths does not preclude their future development, and preventive measures are indicated.

Cystinuria is thought to be inherited as a sex-linked trait. However, in Newfoundland it is transmitted as a simple autosomal recessive trait. The defect has also been reported in Dachshunds, Basset Hounds, English Bulldogs, Chihuahuas, Yorkshire Terriers, Irish Terriers, and mixed-breed dogs. Cystinuria has been recognized almost exclusively in male dogs, except in Newfoundlands. A urine cystine concentration of >75 mg/g creatinine in nonfasted dogs is predictive of susceptibility to cystine urolithiasis.

Cystine solubility depends on urine pH, with solubility increasing rapidly when urinary pH is >7.5. Dogs fed meat-based diets tend to excrete acidic urine, which leads to urine cystine supersaturation.

Cystinuria is a lifelong defect of tubular reabsorption and cannot be cured. Cystine stones tend to recur within 1 yr without management to prevent recurrence, and they often recur despite attempts at prevention.

Dissolution and Prevention Protocols: Urinary cystine output should be reduced. Protein-restricted alkalinizing diets have been associated with reducing the size of cystine urocystoliths. Urinary cystine concentration can also be reduced by administering N-(2-mercaptopyrionyl)-glycine (2-MPG, tiopronin) or penicillamine. 2-MPG should be given at 15–20 mg/kg, PO, bid, for dissolution, and at 10–15 mg/kg, PO, bid, for prevention. Penicillamine (15 mg/kg, PO, bid) can be substituted for 2-MPG; unfortunately, ~40% of dogs treated with penicillamine exhibit anorexia and vomiting. The vomiting may be partially resolved by giving the medication with meals; however, a severe reduction in dosage or complete withdrawal is often necessary.

The urine should be alkalinized to a pH >7.5. Sodium bicarbonate added to the diet at 1 g (¼ tsp)/5 kg, tid, readily accomplishes this, but because sodium supplementation may enhance cystinuria, potassium citrate (20–75 mg/kg, PO, bid) is preferred.

Urine volume can be increased by mixing water with the food. Salt should not be added to the diet, because increased sodium excretion may cause increased cystine excretion. If urine volume is adequate and the urine pH is maintained above 7.5, most cystinuric dogs will pass urine that is only slightly supersaturated or undersaturated

for cystine. Under such conditions, only relatively small doses of 2-MPG or penicillamine may be necessary to achieve 24-hr undersaturation.

Silica Stones: Early reports indicated a predominance of silica stones in German Shepherds, but many breeds have now been implicated. Urethral obstruction in males is the most common presenting problem, but signs similar to those associated with other types of uroliths also may be noted. The mean age at occurrence is ~6 yr. The stones are usually multiple and develop in the bladder and urethra. Silica uroliths are radiopaque. They frequently, but not always, have a characteristic "jackstone" appearance. Identification requires spectrographic analysis and cannot be made with kits for qualitative stone analysis.

The role of diet in spontaneously occurring silica urolithiasis has not been determined, although plants are often an abundant source of silica. If the diet of an affected dog is known to be high in silica, or if silica urolithiasis has been recurrent, a dietary change should be recommended. Only general management principles can be suggested for silicate urolithiasis. Additional salt and/or water should be added to the diet to induce diuresis and to lower the urine solute concentration. When present, urinary tract infections should be eliminated. Diets high in plant proteins should be avoided.

Feline Lower Urinary Tract Disease

(Feline urologic syndrome)

Hematuria, pollakiuria, and stranguria are the characteristic clinical signs of feline lower urinary tract disease (FLUTD) in cats. Although the specific underlying cause of this common syndrome is often not identified, associated conditions include urinary tract infection, neoplasia, trauma, urethral plugs, urolithiasis, and sterile cystitis (feline interstitial cystitis).

Feline Urolithiasis: Feline urolithiasis is a common disease seen with equal frequency in both sexes. Until recently, it was thought that most uroliths in cats were small and resembled sand or were gelatinous plugs that differed from typical uroliths in that they contained a greater amount of organic matrix, giving them a toothpaste-like consistency. Matrix-crystalline plugs are most commonly found within the urethra near the urethral orifice and are primarily responsible for urethral obstruction. Recently, prevalence of urolithiasis

with grossly observable stones composed primarily of calcium oxalate has increased in cats. The most common feline uroliths are calcium oxalate, magnesium ammonium phosphate, and urate.

Urolithiasis is usually suspected based on clinical signs of hematuria, dysuria, or urethral obstruction. Urinalysis, urine culture, radiography, and ultrasonography may be required to differentiate uroliths from urinary tract infection or neoplasia. Radiography, cystoscopy, or ultrasonography are critically important to detect uroliths, because only ~10% of feline urocystoliths can be detected by abdominal palpation. Uroliths with a diameter >3 mm are usually radiodense; however, because smaller uroliths are common, double-contrast radiography may be required for detection. Radiographic evidence of uroliths is seen in ~20% of cats with hematuria or dysuria.

The usual clinical approach to grossly observable urocystoliths is surgical removal or lithotripsy where available, followed by dietary therapy instituted as a preventive measure. For sterile struvite uroliths, medical dissolution is the preferred treatment. Nephrolithiasis is not associated with an increase in the rate of progression of feline kidney injury, and cats with nephrolithiasis are generally managed without surgery.

Calcium Oxalate Stones: Calcium oxalate uroliths are the most common feline uroliths and the most common nephrolith, although their underlying cause is unknown. Common management schemes that involve feeding urine-acidifying diets with reduced magnesium have reduced the incidence of feline struvite urolithiasis. Magnesium has been reported to be an inhibitor of calcium oxalate formation in rats and people; thus, the reduced magnesium concentration in feline urine may partially explain the increase in calcium oxalate stones in cats.

Medical protocols that promote calcium oxalate dissolution are not known; therefore, surgery and lithotripsy are the primary means for removal (small bladder stones may be eliminated by voiding urohydropulsion). However, some calcium oxalate uroliths, especially those in the kidneys, may not cause clinical signs for months to years. Because of the unavoidable destruction of nephrons during nephrotomy, this procedure is not recommended unless it can be established that the stones are a cause of clinically significant disease. Recurrence remains problematic. A variety of diets has

been formulated to restrict the formation of calcium oxalate uroliths and should be considered appropriate for maintenance in cats with nephroliths and after the removal of urocystoliths. Diets that reduce the likelihood of formation of both struvite and calcium oxalate stones are commercially available. Eliminating any associated urinary tract infections, avoiding mineral and vitamin C and D supplementation, and encouraging water consumption are critical.

Struvite Stones: Three distinct types of struvite uroliths are recognized in cats: amorphous urethral plugs with a large quantity of matrix, sterile struvite uroliths (which form perhaps as a result of certain dietary ingredients), and struvite uroliths that form as a sequela of urinary tract infection with urease-producing bacteria. Struvite uroliths induced by infection are less common than sterile struvite uroliths. An additional type of struvite urolith in cats consists of a sterile struvite nidus that predisposes to urinary tract infection with urease producing bacteria and subsequent formation of infected struvite laminations around the sterile nidus.

Treatment of sterile struvite urolithiasis focuses on reducing the urine pH to ≤ 6 and on reducing the urine magnesium concentration by feeding magnesium-restricted diets. Reducing urine pH and magnesium concentration is best accomplished by feeding a commercially available prescription diet formulated for this purpose. Some diets are formulated to reduce the formation of both struvite and calcium oxalate stones. Generally, neither sodium chloride nor urine acidifiers should be given concurrently with these diets, because they are already supplemented with sodium chloride and formulated to produce aciduria. In addition, these diets should not be fed to cats that are acidemic, have azotemia of any cause, or have cardiac dysfunction or hypertension. Urolith size should be monitored every 4 wk by radiographs or ultrasonography, and crystalluria by urinalysis. Struvite crystals should not form if therapy has been effective in producing urine that is undersaturated with magnesium, ammonium, and phosphate. Because small uroliths may not be detected radiographically, the calculolytic diet should be continued for ≥ 4 wk after radiographic documentation of urolith dissolution. If treatment does not induce complete dissolution of uroliths, it is likely that either the wrong mineral component was identified, the nucleus of the urolith is composed of a different mineral than the outer portion of the urolith, or the owner

is not complying with therapeutic recommendations.

Other Feline Stones: Ammonium urate, uric acid, calcium phosphate, and cystine uroliths are less common in cats, but ammonium urate and uric acid account for $\sim 6\%$ of feline uroliths. Although a renal tubular reabsorptive defect and portovascular anomalies have been incriminated as causes in a few cases, the cause of most urate uroliths in cats has not been established. Nonetheless, formation of highly acidic and concentrated urine associated with consumption of diets high in purine precursors (especially liver) appears to be a risk factor.

Medical protocols that consistently promote dissolution of ammonium urate uroliths in cats have not been developed, and surgery remains the most common method of removal. For small stones, voiding urohydropulsion may be effective. Prevention should include feeding a diet low in purine precursors and promoting formation of less acidic urine that is not highly concentrated. Although allopurinol may reduce the formation of urate in cats, studies of the efficacy and potential toxicity of allopurinol in cats are required before meaningful guidelines can be established.

Sterile Cystitis (Feline Interstitial Cystitis):

Feline interstitial cystitis is generally taken to be synonymous with sterile cystitis of unknown cause. The underlying cause of this disorder is unknown, although anxiety and altered neurohormonal factors have been implicated.

Diagnosis is by exclusion of other causes of lower urinary tract disease in cats, such as obstruction by urethral plugs, bacterial urinary tract infection, neoplasia or other mass lesions, and urolithiasis. Diagnostic tests to exclude these conditions may include radiographs, ultrasonography, urinalysis, urine culture, and cystoscopy.

Because the cause of feline interstitial cystitis is unknown, the goal of treatment is to reduce the severity and frequency of episodes of cystitis. Therapeutic considerations include reduction of stress through environmental changes, dietary adjustments (eg, use of canned preparations), pheromones applied topically in the environment, and analgesics (eg, butorphanol, 0.2–0.4 mg/kg, PO, bid-tid). Other medications (eg, amitriptyline, 5–12.5 mg/cat, PO, once or twice daily; clomipramine, 0.5 mg/kg/day, PO; fluoxetine, 1 mg/kg/day, PO) have yielded mixed results.

BEHAVIORAL MEDICINE INTRODUCTION

An animal's "behavior" is the product of its genetic composition, the environment in which the animal functions, and the animal's experience (particularly in the pre- and postnatal environment through the primary socialization period). This section focuses primarily on the diagnosis and treatment of abnormal behavior of domestic animals. For each species, normal social behavior

is outlined, followed by a description of common behavioral disorders.

The minimum behavioral welfare requirements for the housing and enrichment of farm, zoo, and laboratory animals, known as the five freedoms, are equally important for family pets. These include freedom from hunger and thirst; discomfort; pain, injury, or disease; fear and distress;

and freedom to express normal species behaviors. When these needs are not fully addressed, welfare is compromised and both health and behavior problems arise.

In companion animals, behavior problems weaken the pet-owner bond, resulting in a decreased owner commitment to pet care. They are a primary reason for pet relinquishment and euthanasia. Yet studies show that many owners do not report behavior changes to their veterinarian, and most veterinarians neglect to inquire about them. Thus, screening for any behavioral changes or emerging behavior problems should be done at each veterinary visit to ensure that the behavioral health, physical health, and welfare of the pet are being effectively and humanely managed.

INTEGRATING BEHAVIORAL SERVICES INTO VETERINARY PRACTICE

Each veterinary visit should include screening questions to determine whether there are any behavior concerns or any change in behavior from previous visits. In addition to enabling the veterinarian to assess the health and welfare of the pet, this initiates a dialogue with clients about behavior and lets them know that behavior is central to good veterinary care. Recording responses to behavior questions at each visit allows a baseline to be established for future comparison.

A basic behavior screening questionnaire is a simple way to collect information. Questionnaires should be standardized so no topic is left uncovered and so data can be compared from visit to visit. When used continually from the pet's first visit, these tools allow for early detection and intervention. Addressing behavioral concerns early provides the best chance to manage the problem and prevent a minor issue from becoming more serious and deeply entrenched. If behavioral signs (eg, barking, growling, lunging, housesoiling) are identified during the visit, the veterinarian will need to determine whether there are underlying medical issues, whether the behaviors are normal and in context or abnormal and out of context, and whether they are manageable for the household, either to begin offering behavior guidance or, when indicated, to refer the client for further counseling.

Behavioral services should be offered using an integrated team approach. Staff can help with behavioral screening (questionnaires) and provide pet selection

advice and preventive guidance for new pet owners. Veterinarians or staff with sufficient skills and training can offer client education about how to prevent and manage undesirable behaviors and classes to help pet owners socialize and train their pets. A good set of resource materials and links to Web sites that provide appropriate and sound behavioral guidance can supplement the advice provided.

Veterinary behavioral technicians can oversee the preventive counseling and training services offered by a veterinary hospital. They can also play an integral role during behavioral consultations by taking the history, demonstrating behavior modification techniques and products, and conducting case followup and ongoing support. Information sources for veterinarians, technicians, and staff interested in veterinary behavior are listed in TABLE 1.

Veterinarians also have a vested interest in how clients train their pets. Trainers should have a sound background on species-typical behaviors, as well as how behaviors can be shaped and modified through the principles of learning that apply to all species. The Association of Pet Dog Trainers, the American Humane Association, and the American Veterinary Society of Animal Behavior have published guidelines for appropriate and humane training and behavior modification. Certified trainers can be found at www.ccpdt.org and www.karenpryoracademy.com, and advocates of force-free dog training at www.petprofessionalguild.com. However, even with a certified trainer, veterinarians should observe and talk with the trainer to ensure that the methodologies used are humane, effective, and appropriate for the individual owners and pets. Having an active discussion about training with each dog owner can help the owner to understand the principles of learning and how to differentiate those trainers who use undesirable techniques from those who use humane, reward-based techniques.

GLOSSARY OF BEHAVIORAL TERMS

Abnormal Behavior: These activities show dysfunction in action and behavior. Alternatively, the terms behavior problem, behavior pathology, mental health disorder, or emotional disorders might be used. By comparison, many behavioral complaints are normal behaviors that are undesirable to owners (eg, garbage raiding, jumping up, predation, herding, guarding).

Abnormal Repetitive Behaviors:

Abnormal repetitive behaviors are a heterogeneous group of behaviors that include both stereotypes and compulsive/impulsive behaviors (*see below*). Although these two categories of behavior have similarities in clinical presentation and perhaps neurophysiology, they are not synonymous. In addition, underlying medical conditions might cause or contribute to these signs. Thus, until a definitive diagnosis is made, the term abnormal repetitive behavior is a descriptive term for any of the behaviors that are maladaptive, repetitive or fixed, and pathologically abnormal. Although categories overlap, clinical signs have been described as oral/ingestive (eg, pica, polyphagia, licking, gulping), neurologic/hallucinatory (eg, fly snapping, light chasing), locomotory (eg, spinning, pouncing), and self-directed (eg, acral lick dermatitis, psychogenic alopecia).

Aggression: Aggression can be defined in a narrow sense (attack) or in a broader sense as agonistic behavior. In the latter case, aggression can be appropriate or inappropriate, in context or out of context, inter- or intraspecific, or a challenge or contest that results in deference or in combat and resolution.

Anxiety: Anxiety is the apprehensive anticipation of future danger or misfortune,

which may be accompanied by both behavioral and somatic signs (vigilance and scanning, autonomic hyperactivity, increased motor activity and tension).

Compulsive or Obsessive-Compulsive Disorders:

Compulsive behaviors are abnormal and repetitive, may be variable in form, and are often fixated on a goal. They may be exaggerated, sustained, intense, and difficult to interrupt or have an element of dyscontrol in either the initiation or continuation of the behavior or the inhibition or switching between behaviors. They are generally derived from normal behaviors such as grooming, predation, ingestion, or locomotion. Compulsive disorders might initially arise in situations of frustration or conflict but become compulsive when they persist or arise outside the original context. There appears to be a genetic predisposition to the development of certain compulsive behaviors (eg, wool sucking in Oriental breeds of cats, tail chasing in German Shepherds, flank sucking in Dobermans). There is likely an alteration in serotonergic activity for most compulsive disorders in dogs and cats. However, there can be a wide range of presentations, and multiple neurotransmitters have been implicated (eg, dopamine, opiates). This may indicate an altered course of disease over time or that the diagnosis encompasses more than one disorder. Drugs that inhibit serotonin

reuptake are generally most effective to enhance serotonin transmission and inhibit dopamine activity. Brain areas of interest include the prefrontal cortex and amygdalae.

Conflict: Conflict arises when a pet has competing motivations or is motivated to perform more than one opposing behavior. This might occur when a dog is motivated to greet but is fearful of approach, perhaps because of previous unpleasant experiences (eg, yelling, hitting, pinning). The resultant behavior might be either a displacement behavior (*see below*) or aggression (when fear is an overriding factor).

Displacement Behavior: This type of activity is generally a normal behavior that is performed out of context, or is “displaced,” because the animal is unable—physically or behaviorally—to execute another activity or otherwise occupy itself. This is less specific than redirected behavior (*see below*), in which the intended behavior is directed toward another target. When displacement activity occurs, the behavior may be out of context with the situation (eg, circling, air snapping, or even urination). Displacement behaviors may arise from conflict or frustration or be a vacuum activity.

Dominance: Dominance is a concept frequently misapplied. The ethological concept of dominance refers to competitive control over a resource in a limited circumstance and to the ability of a higher-ranking animal to displace a lower-ranking one from that resource. Rank is usually defined by an ability to control the resource or by access and ability to restrict matings; however, extra-pair copulation is almost always more common when assessed by DNA analysis than it was believed to be on the basis of behavioral observations.

Dominance is not interchangeable with hierarchical rank. Ranks, particularly those that are linear and in which a “dominant” animal is identified, are largely artifacts of experimental or manipulated situations. A “dominant” animal is *not* the one engaged in the most fighting and combat. Most high-ranking animals seldom have to contest their right of access to a resource. Instead, high-ranking animals are usually better identified by the character and frequency of deferential behaviors exhibited by others in their social group and by their ability to respond appropriately to a variety of social and environmental circumstances. Thus, confident and assertive postures and

signaling of one individual in a pair might be described as dominant if the response of the second individual is deferent or subordinate. However, dominant/subordinate does not describe the relationship between the pair, unless the response is consistent across resources and interactions. While this terminology applies to communication and signaling between members of a species (eg, dog-dog), it does not “translate” to communication between species (eg, dog-human).

Fear: Fear is a feeling of apprehension associated with the presence or proximity of an object, individual, or social situation. Fear is part of normal behavior and can be an adaptive response. The determination of whether the fear or fearful response is abnormal or inappropriate must be determined by context. For example, fire is a useful tool, but avoidance of fire is an adaptive response. If a pet is fearful of stimuli that are innocuous, such as walking on certain types of surfaces or going outdoors, such fear would be irrational and, if it were constant or recurrent, probably maladaptive. Fears usually occur as graded responses, with the intensity of the response proportional to the proximity of the stimulus. A sudden, all-or-nothing, profound, abnormal response that results in extremely fearful behaviors is usually called a phobia.

Frustration: This state arises when an animal is motivated to engage in a sequence of behaviors that it is unable to complete because of physical or psychological obstacles in the environment. When pets are frustrated—such as a cat that cannot gain access to an outdoor cat that it sees through the window, or a dog that cannot get to a stimulus on the other side of a door or fence—the resultant behavior can be a redirected behavior (eg, attack of another family pet or owner), a displacement behavior (eg, stereotypic pacing), or signs associated with anxiety (eg, whining or howling). Another example of goal frustration is the dog or cat that chases a laser light toy but is unable to finish the sequence or achieve any goal. This frustration may lead to obsessive chasing of other lights and shadows.

Phobia: Most fearful reactions are learned and might be unlearned with gradual exposure, although a lack of sufficient previous exposure, consequences of previous exposure, and genetic factors all play a role in how quickly or completely the unlearning might be achieved. Phobias involve sudden, all-or-nothing, profound,

abnormal responses that result in extremely fearful behaviors (catatonia, panic). Phobias may develop over time—some animals develop increasingly more intense fears with repeated exposure (eg, storm phobias). However, once established, they are associated with immediate and intense anxiety when the stimulus is presented. Once a phobic event has been experienced, any event associated with it or the memory of it is often sufficient to generate the response (eg, wind, rain, or darkening sky and storm phobias). Although fears may diminish with repeated exposure and no untoward consequences, phobias can remain at or exceed their former high level for years even without reexposure. The genesis for such events in dogs is usually either extremely frightening or traumatic, or the dog itself has profound internal problems with fear (eg, genetic predisposition) so that responses to unfamiliar stimuli are excessive. Owner responses might inadvertently aggravate the problem, either by further encouraging the behavior or by adding to the fearful emotional state if the outcome for the pet is unpleasant (eg, owner anger or punishment). Phobic situations are either avoided at all costs or, if unavoidable, are endured with intense anxiety or distress.

Redirected Behavior: Redirected behavior activities are directed away from the principal target and toward another, less appropriate target. When the animal is in a state of emotional arousal and is unable to reach the appropriate target, the behavior can be redirected to an alternative target if the animal is interrupted.

Stereotypic Behaviors: A stereotypy is a perseverant repetition of behaviors that are unvaried in sequence and have no obvious purpose or function. They usually derive from contextually normal maintenance behaviors (eg, grooming, eating, walking). The behaviors have been reported commonly in farm, zoo, and laboratory animal species and arise in situations of conflict or frustration related to confinement or husbandry practices. They may arise when the environment is barren or stress evoking, when the animal lacks the opportunity to display a full range of species-typical behaviors, with maternal deprivation, and as a result of neurologic disorders. It is thought that some stereotypic behaviors, at least in their early stages, may provide a mechanism for the pet to cope. For example, nonnutritive suckling in calves may assist digestive processes.

Stereotypys might be associated with basal ganglia dysfunction and can be induced by dopaminergic stimulation of the striatum.

Vacuum Activity: When an animal is highly motivated to perform an instinctive behavior but there is no available outlet, a vacuum activity may be exhibited (flank sucking, licking, etc). These activities have no apparent useful purpose.

DIAGNOSIS OF BEHAVIORAL PROBLEMS

Veterinarians must have an understanding of the behavior and development of the species, the principles of learning, and the signs of fear and anxiety to differentiate normal behavior from abnormal behavior. When presented with an animal with undesirable behavior, the first step is to exclude any medical problems that might be causing or contributing to the behavioral signs. In addition, while it is common to consider the effects of disease on behavior, stress can cause alterations in behavioral, physiologic, and immune responses, which can have variable effects on health and behavior with increasing chronicity. Stress leads to alterations in the hypothalamic-pituitary axis and in levels of dopamine, serotonin, norepinephrine, and prolactin. In animals, stress can cause or contribute to feline interstitial cystitis; dermatologic, respiratory, and GI disorders; and behavior problems such as compulsive disorders, exaggerated fear responses, and psychogenic polydipsia and polyphagia.

Diagnosis of any behavioral problem requires the identification of all behavioral and medical signs, history taking, a physical and neurologic examination, and any diagnostic tests indicated to exclude underlying medical conditions that might cause or contribute to the signs (*see* TABLE 2).

If there is no underlying medical cause for the behavioral signs, then a comprehensive behavioral history is required to determine the diagnosis, prognosis, and treatment options. The history should include: 1) sex, breed, and age of animal (breed predispositions); 2) age at onset of condition or complaint; 3) duration of condition or complaint; 4) description of undesirable behavior; 5) frequency (hourly, daily, weekly, monthly); 6) duration of bouts; 7) any changes in pattern, frequency, intensity, and duration of bouts; 8) corrective measures tried and the response, if any; 9) any activities that stop the behavior (eg, animal collapses); 10) 24-hr schedule of animal and

TABLE 2 MEDICAL CAUSES OF BEHAVIORAL SIGNS

Medical Condition	Behavioral Signs
Illness or disease	Altered personality, lethargy, depression, withdrawal, anorexia, reduction in grooming, altered social relationships, altered response to stimuli
NEUROLOGIC	
Central (affecting forebrain, limbic/temporal, and hypothalamic), rapid-eye movement sleep disorders	Altered awareness and response to stimuli, loss of learned behaviors, housesoiling, disorientation, confusion, altered activity levels, temporal disorientation, vocalization, change in temperament (fear, anxiety, aggression), altered appetite, altered sleep cycles, interrupted sleep (aggression/waking/activity)
Peripheral (neuropathy)	Self-mutilation, irritability, aggression, circling, hyperesthesia
Focal seizures/temporal lobe seizures	Repetitive behaviors, self-trauma, chomping, staring, altered temperament (eg, intermittent states of fear or aggression), tremors, shaking, interrupted sleep
Sensory dysfunction	Altered response to stimuli, confusion, disorientation, altered sleep cycles, irritability, aggression, vocalization, housesoiling
METABOLIC / ENDOCRINE	
Feline hyperthyroidism	Irritability, aggression, urine marking, increased activity, night waking
Canine hypothyroidism	Lethargy, decreased response to stimuli, irritability, aggression
Hyperadrenocorticism	Panting, night waking, housesoiling, irritability, polyphagia, anxiety
Diabetes/hyperglycemia	Housesoiling, night waking
Functional ovarian and testicular tumors	Androgen-induced behaviors: males—aggression, roaming, marking, sexual attraction, mounting; females—nesting or possessive aggression of objects
Hepatic or renal encephalopathy	Signs associated with affected organ, anxiety, irritability, aggression, altered sleep, housesoiling, mental dullness, decreased activity, restlessness, increased sleep, confusion
Anemia or electrolyte imbalances	Pica
Pain	Altered response to stimuli, decreased activity, restlessness/inability to settle, vocalization, housesoiling, aggression, irritability, self-trauma, waking at night
Gastrointestinal	Licking, polyphagia, pica, coprophagia, housesoiling (fecal), wind sucking, tongue rolling, unsettled sleep, restlessness
Urogenital	Housesoiling (urine), polydipsia, waking at night
Dermatologic	Psychogenic alopecia (cats), acral lick dermatitis (dogs), nail biting, hyperesthesia, other self-trauma

owner, as well as any day-to-day variability; 11) environment and housing; 12) animal's familial history; and 13) anything else the owner thinks is relevant. In farm animals, questions should be framed within the context of the problem so that housing, management, group or herd behavior, production, and perhaps reproduction are addressed.

For each behavior problem, the "ABC" should be considered, ie, the antecedent, or what precedes the behavior; the behavior, or the description of the problem; and the consequences, or what happens immediately after the behavior. With maturity and learning, the animal's response to a stimulus may be modified; thus, the initial events may be just as important to evaluate as the more recent events.

History might be collected in part by having the owner complete a history questionnaire before the visit, especially with respect to data about the home and housing, family, daily schedule, training, husbandry, and background. However, further interactive questioning and discussion with those responsible for the animal's care, housing, and training are required to further evaluate the progress and development of the problem from the initial event to the present time. Having the owners bring video clips of the behaviors can further help provide insight as to the diagnosis, prognosis, and how the problem might be managed or improved.

Additional information about the pet's personality, relationship with the owner, response to stimuli, and owner's response might be gained during the visit by observation of the pet and how it interacts with the owners. Although provoking the pet is generally contraindicated because any further repetition of the problem is ill advised for the pet and might lead to further learning, a controlled interactive assessment might include how the animal responds to other animals and people, sounds, a child-like doll, or handling, including physical examination, petting, or the application of products such as a head halter, muzzle, or body harness. The pet's response to commands can be assessed during the visit, as well as the types of treats or toys most likely to positively affect the pet.

PROGNOSIS OF BEHAVIORAL PROBLEMS

Client understanding and compliance are critical if animals with behavioral disorders are to improve. Because the strategy to

modify undesirable behavior requires that the owner be prepared and capable of identifying each situation and substituting a more desirable response, the initial approach should be to avoid or prevent the provocative situation. The predictability of the problem, the ability of the owners to implement initial preventive strategies, the expectations as to what might be achieved, the pet's temperament, how the pet's behavior will need to be modified over time, and the practicality of implementing the program considering the environment, family, and pet should all be reviewed and must be both acceptable and practical for the owners. In addition, special consideration will need to be given in cases of aggression to evaluate risk and ensure safety. (For guidelines on risk factor assessment, *see* www.esvce.org.)

TREATMENT OF BEHAVIORAL PROBLEMS

In production animals, treatment focuses on group management, environmental or housing modifications, and in some cases removing individual animals out of or to other groups. Specifics are covered in the relevant species discussions.

In companion animals, the treatment of behavior problems varies with diagnosis and prognosis. In general, the program begins with prevention and avoidance of problems, while the owner develops effective strategies to modify the pet's behavior so that it might gradually be reintroduced to the problem situations while achieving a desirable outcome. Initially, prevention is necessary to avoid further compromising the pet's welfare and to ensure safety in cases of aggression. Repetition of the behavior further aggravates the problem if the pet successfully accomplishes its intended goal (eg, escape or retreat from the stimulus), while each exposure in which the outcome is unpleasant can condition further anxiety. Improvement is generally a slow and gradual process; therefore, owners must have realistic expectations of what might be achieved. Modifications to the environment may be required, so that the pet can be kept away from the stimuli (or the sights or sounds of the stimuli) that incite the problem or from the areas in which the problem occurs. Modifying the pet's behavior is accomplished by applying the principles of learning and behavior modification, primarily achieving and rewarding desirable outcomes along with use of products that improve safety, reduce anxiety, or help to achieve the

desired response more effectively (eg, muzzles, head halters, no-pull harnesses, etc). Drugs and natural products may also be indicated for some pets and some problems.

Behavior Modification Principles

The most commonly used behavioral techniques include habituation, extinction, desensitization, counterconditioning, response substitution, and shaping. Flooding is often talked about but seldom used because it is likely to make most animals worse. While punishment is frequently used with varying degrees of success, few people correctly use this technique, and there are both humane and safety issues with the use of positive punishment. For punishment to be successful, the aversive stimulus (eg, startling with a loud noise, spraying compressed air) must occur sufficiently close to the onset of the behavior that the probability of the behavior occurring in the future is lessened. Often, punishment is more about the owner's anger than about changing the behavior. In addition, some dog owners have been ill advised by training advice that advocates confrontation, with the intent of asserting leadership (dominance). In fact, numerous studies have demonstrated that punishment-based training and confrontational techniques are more likely to lead to fear, avoidance, and increased aggression.

Most of the humane, passive, or positive techniques involved in behavior modification are not hard to learn and together with preventive strategies are very successful. In fact, dogs trained with rewards have fewer behavior problems, less fear, and less avoidance than dogs trained with punishment. The following is a short review of the basic principles involved in the techniques and their associated strategies.

Classical Conditioning: The pairing of an unconditioned stimulus with a neutral stimulus results in a conditioned stimulus and a conditioned response. Classical conditioning can occur in both positive and negative ways. Examples of a positive conditioned emotional response are the pairing of a clicker with favored treats (for clicker training) or a doorbell signaling visitors (for pets enthused about meeting new people).

Problems arise when a fearful conditioned emotional response is established toward a previously neutral stimulus (visual, odor, auditory, animate, inanimate) by repeated pairing with a fear-producing stimulus. Once this occurs, the stimulus itself will elicit the fear response, eg, a

doorbell paired with the arrival of unfamiliar people (for pets fearful of visitors), or a doorbell paired with verbal or physical discipline applied by the owner for barking or jumping up (pinning, leash corrections). Similarly when a pet lunges or barks when meeting new people on the street or at the front door, the use of positive punishment to inhibit the behavior (such as choke collars, prong collars, shock, pinning) may condition a new response in which unfamiliar people become a fear-evoking conditioned stimulus. A visit to the veterinary clinic that may begin as a neutral situation may quickly become fear evoking if it is associated with unpleasant outcomes or is further enhanced by owner anxiety. In addition, all of the stimuli associated with the event (sights, sounds, smells) also become conditioned stimuli for fear. In much the same way, rain, wind, darkening skies, and lightning can quickly become conditioned fear-evoking stimuli for pets fearful of thunder.

Counterconditioning and Desensitization:

Counterconditioning involves the consistent and repeated pairing of a stimulus that evokes an unpleasant response with something that is emotionally positive until a positive association is made. To be successful, counterconditioning should be coupled with desensitization in which the stimulus is minimized or reduced to a level that does not evoke the fear response (eg, by reducing volume, increasing distance, changing the environment, or modifying the stimulus to something less threatening). Once a positive association is made, rewards can be paired with stimuli of gradually increasing intensity.

Desensitization and counterconditioning are extremely time consuming. The exercises must be constantly repeated, so that the response is altered to a positive one. All stimuli that evoke fear (sights, sounds, odors, tactile) must be considered. Clients often want both quicker fixes and less work. However, moving too quickly provokes anxiety and sabotages any behavior modification program.

Operant Conditioning: Operant conditioning is a method based on making an association between a behavior and consequences of that behavior. The results either increase or decrease the likelihood of future responses. There are four types of behavior/consequence relations: positive and negative punishment and positive and negative reinforcement. Reinforcement increases the likelihood a behavior will be repeated, and punishment leads to a

reduction in behavior. Negative refers to the removal of a stimulus, and positive refers to the application of a stimulus.

Positive reinforcement training occurs if behavior is increased by something applied (generally something pleasant or appealing); **negative reinforcement** occurs if behavior is increased by something removed (generally something unpleasant). In positive reinforcement training, a reward should be given immediately and consistently until the behavior is reliably repeated. If the behavior is to be trained on command or cue, a word or hand signal should then be added before the behavior-reward sequence. Once learned, behavior can be reinforced on a variable schedule, so that the period of time or number of responses before the reward is given is varied. Rewards are used for positive reinforcement, but a reward is not synonymous with positive reinforcement. A reward is anything desirable to the pet, from an activity such as petting, walking, or play, to an item such as a toy, food, chew, or treat. However, unless there is a clear relationship between the behavior and the reward (timing, consistency, contiguity), then the reward does not achieve the goal of positively reinforcing behavior.

Negative reinforcement must not be confused with punishment, because punishment decreases behaviors and reinforcement increases behaviors. One example of negative reinforcement is avoidance or escape behavior. For example, if an animal anticipates an unpleasant outcome (eg, meeting another dog, veterinary visit), then the aversive outcome will not occur if the animal retreats. Similarly, if the owner puts pressure on a head halter until the desired behavior is achieved (eg, sit, back up), the release of tension is negative reinforcement. One potential consequence of negative reinforcement is that if a pet's threats or aggression lead to removal of a stimulus (eg, dog, delivery person, owner), the behavior is reinforced by the retreat of the stimulus.

Positive punishment occurs when a behavior decreases when something is applied (generally something unpleasant), and **negative punishment** occurs when a behavior is decreased when something is removed (generally something pleasant or appealing). In positive punishment, if behavior does not decrease after the first few applications, then the punishment is not being appropriately timed or the behavior is too strongly motivated to be deterred by punishment. Positive punishment applied by a person (owner, trainer) is intended to cause the pet to

become fearful of repeating the behavior. However, a potential consequence is that the pet becomes fearful or defensive to the punisher or to an approaching hand. Relationships with people should always remain positive! Also, if an unpleasant consequence occurs only when the owner is present, the behavior may continue in the owner's absence. Another problem with positive punishment is that punishment paired with exposure to a stimulus (barking at cars, meeting other dogs on walks) can result in a conditioned fear of the stimulus (*see above*).

Punishment cannot be used to achieve desirable behaviors, only to stop what is undesirable. If the goal is to make the pet fearful of repeating a behavior (eg, garbage raiding, taking things from counters, chewing plants) or to keep the pet away from an area (room, couch, bed), then environmental punishment or pet-activated punishment (eg, motion detector alarms or sprays, upside-down carpet runners, aversive tastes, double-sided tape, or bark-activated sprays) or remote punishment (eg, spraying water while out of sight, remote-activated alarm or spray) might be most appropriate. However, before focusing on how to stop what is undesirable, the owner should first focus on providing a desirable alternative (eg, where to sleep, where to climb, what to chew).

Negative punishment is the reduction of a behavior by the removal of something pleasant. For example, if the pet is receiving affection or play when an undesirable behavior begins (eg, play biting, mouthing, mounting), the immediate removal of the play or affection will "negatively" punish the pet. However, unless the pet can determine what behavior leads to the removal of play, the behavior may actually intensify because of frustration at not receiving its reward.

Second-order Reinforcers: Signals that can be used at a distance to convey that the reward is coming are second-order reinforcers. Commonly used second-order reinforcers are words (eg, "Good dog!"), clickers, or whistles. By repeatedly and continuously pairing these with a primary reward such as a toy or treat, second-order reinforcers can elicit the same response that the reward would, as long as the pairing is repeatedly maintained. Clicker training requires frequent practice and excellent timing, but once achieved the animal can be reinforced each time the desired behavior is observed. Clicker training is an excellent way to immediately "mark" desirable responses, gradually shape new or more desirable behaviors

(eg, longer, more relaxed), or associate a positive emotional response with the stimulus. (A useful resource is www.clickertraining.com.)

Premack Principle: When a more desirable behavior is made contingent on a less desirable behavior, the less desirable behavior is more likely to be repeated. Thus, the more desirable behavior serves as the reinforcer. For example, if a pet wants to go out or cross the street for its walk, the owner can train a sit-stay before each of these behaviors. A horse or dog that wants to walk ahead can be taught that walking on a slack rein or leash will result in this behavior.

Overlearning: Overlearning is the repeated evocation and expression of an already learned response. It is a phenomenon frequently used in training for specific events but may be underused in preventing fearful responses in dogs. Overlearning accomplishes three things: it delays forgetting, it increases the resistance to extinction, and it increases the probability that the response will become a "knee-jerk" one, or response of first choice, when the circumstances are similar.

Shaping: Shaping works through gradual approximations and allows the animal to be rewarded initially for any behavior that resembles the desired behavior. For instance, when teaching a puppy to sit, providing a food reward for a slight squat will increase the probability that squatting will be repeated. This squatting behavior is then rewarded only when it more closely resembles a sit, and finally, when it becomes a true sit. Shaping can also be used to reward an increase in duration of or progressively more relaxed behaviors.

Extinction: The ending of a behavior once all reinforcement is removed is termed extinction. For example, if people pet a dog that jumps up on them for attention, the behavior continues; if they stop, the dog will eventually extinguish its response because the reward is no longer there. However, any form of intermittent reinforcement—even occasional petting of the dog in response to its jumping—will prolong the performance of the response. Valuable rewards, a long history of performance, and intermittent reinforcement all increase resistance to extinction. Owners also must be prepared for the intensity of the behavior to initially increase before it is extinguished. Giving in will make extinction even more difficult as

the animal learns that higher intensity behaviors achieve the desired outcome.

Habituation: Habituation is a gradual lessening of a response to a stimulus. Usually this occurs with repeated presentation of a stimulus whereby the animal learns that it does not signal anything important. For example, horses placed in a pasture bordering a road may at first run away when traffic passes but eventually learn to ignore it. Stimuli associated with potentially adverse consequences are more difficult to extinguish with habituation than other stimuli. In prey species, responses to sounds associated with predators would be difficult to habituate, because they have been selected for and generally are adaptive. If the fear response is too intense, instead of habituation the animal may become increasingly more fearful of the stimulus. This is termed **sensitization**.

If an extended interval has occurred since the time an animal last experienced a stimulus to which it had habituated, the animal may again react when reexposed to the stimulus. This is termed **spontaneous recovery**.

Flooding: This is used to treat fears of harmless stimuli by forcing the animal to stay in the presence of the stimuli until the fear is extinguished. This procedure is seldom effective and has welfare implications in dogs, because it initially enhances fear and cannot be stopped until all physiologic and emotional signs of fear are gone. If done improperly, flooding may therefore increase problem behaviors. In practice, a controlled level of flooding is quite often used as a component of behavior modification, in which the stimulus is presented at a level that is low enough to cause mild fear and the pet is not removed until it habituates. This can then be combined with reinforcement, ie, the pet is positively reinforced or the stimulus removed (negative reinforcement) when the fear response subsides or abates.

Response Substitution: This involves the replacement of an undesirable response with a desirable one. For example, high-value rewards can be used to train desirable target behaviors that are alternatives to the undesirable behavior. However, if the behavior is part of the pet's natural repertoire (eg, greeting, barking), it can be particularly difficult to train alternative behaviors. Specific examples of response substitution include training a dog to sit or lie down as an alternative to jumping up, mounting, or play

biting; or to sit, walk on loose leash, or back up for dogs forging ahead or running out the door. Training should begin in a variety of environments where success can be most readily achieved. The desired endpoint for the new response is for the animal to be quiet and calm. Therefore, the owner must learn to read the look in the eyes, body posture, facial expressions, and breathing to be able to gradually shape the desired behavior. Training could then move to environments with increasing distractions and locations where the problem is most likely to arise. Alternatively, the pet might be enticed to engage in a behavior that is incompatible with the undesirable behavior, eg, teaching the dog to fetch a toy when visitors arrive instead of jumping up.

To replace the undesirable behavior with one that is desirable, response substitution can be coupled with desensitization by beginning training with stimuli of low enough intensity while training the target behaviors (eg, relaxation) with high-value rewards. However, for pets that are fearful or anxious, the focus should be on desensitization and counterconditioning to change the pet's emotional state rather than the behavioral response.

PRINCIPLES OF PHARMACOLOGIC AND NATURAL TREATMENT

Psychotropic drugs and natural products can be used to reestablish a more stable emotional state and improve trainability in animals that are anxious, fearful, or overly reactive. Drugs might also be effective in the treatment of behavior that is abnormal, pathologic, or lacking impulse control. In addition, drugs may be indicated to improve compromised welfare. However, whereas drugs can improve the animal's emotional state and facilitate new learning, only with concurrent behavior modification can new neuronal pathways be established, new behaviors learned, and fearful responses to stimuli changed to positive ones.

Evidence-based decision making is a way to provide the best information and treatment options. Treatment should be selected using the evidence combined with the clinician's expertise regarding the animal, client, and problem. Very few drugs have been adequately tested in rigorous, randomized, controlled trials for use in veterinary behavioral therapy. In fact, most drugs used in veterinary

behavioral therapy are human drugs, very few of which have had pharmacokinetics established for animal species. This can lead to inaccurate assumptions with respect to dosage, duration of effect, contraindications, and adverse effects. In addition, there is a wide range of published dosages based on the application, individual variability, and desired outcome. Therefore, practitioners should remain current with the most recent veterinary behavior literature with respect to indications, recommended dosages, evidence of efficacy, potential adverse effects, and contraindications before dispensing any of these medications. (For dosing guidelines, see TABLE 3.) Depending on the drug and patient, compounding may be required to achieve an appropriate dosage and formulation for administration; however, reformulation may alter a drug's pharmacokinetics, safety, efficacy, and stability. Recent studies on the use of transdermal preparations of behavioral drugs such as fluoxetine, amitriptyline, and buspirone have found little to no absorption of transdermal preparations versus oral dosing.

A variety of natural products have been used to treat anxiety; however, only a few have demonstrated any evidence to support efficacy. Products that have published studies indicating potential therapeutic effects to calm and reduce underlying fear and anxiety include the canine appeasing pheromone (Adaptil®), the feline cheek gland pheromones (Feliway® and Felifriend®), a feline pheromone that might aid in scratching post training (Feliscratch®), L-theanine (Anxitane®), α-casozepine (Zylkene®), a diet supplemented with α-casozepine and L-tryptophan (Royal Canin Calm™ Feline and Canine), a product combining *Magnolia officinalis* and *Phellodendron amurense* (Harmonease®), a *Souroubea* sp supplement (Sin Susto™), as well as perhaps melatonin, and lavender aromatherapy.

A physical examination and blood and urine tests should be part of a minimum database before dispensing drugs to ensure there are no underlying medical problems that may be causing or contributing to the behavioral signs, or that might have an impact on drug selection and use. For tricyclic antidepressants and selective serotonin reuptake inhibitors, 4 wk may be required to achieve optimal therapeutic effect.

TABLE 3 DRUG DOSAGES FOR BEHAVIORAL THERAPY
IN DOGS AND CATS

Drug	Dog Dosage	Cat Dosage
TRANQUILIZER		
Acepromazine	0.5–2 mg/kg, prn ^a to tid	0.5–2 mg/kg, prn
BENZODIAZEPINES		
Alprazolam	0.01–0.1 mg/kg, prn to qid	0.125–0.25 mg/cat, prn to tid
Clonazepam	0.1–1 mg/kg, bid-tid	0.05–0.2 mg/kg, one to three times/day
Clorazepate	0.5–2 mg/kg, prn to tid	0.2–1 mg/kg, one to two times/day
Diazepam	0.5–2 mg/kg, prn (eg, every 4–6 hr)	0.2–1 mg/kg, prn to tid ^b
Lorazepam	0.025–0.2 mg/kg/day to prn	0.025–0.08 mg/kg, one to two times/day
●xazepam	0.2–1 mg/kg, one to two times/day	0.2–0.5 mg/kg, one to two times/day
TRICYCLIC ANTIDEPRESSANTS		
Amitriptyline	1–4 mg/kg, bid	0.5–2 mg/kg/day
Clomipramine	1–3 mg/kg, bid ^c	0.25–1 mg/kg/day ^c
Doxepin	3–5 mg/kg, bid-tid	0.5–1 mg/kg, one to two times/day
Imipramine	1–4 mg/kg, one to two times/day	0.5–1 mg/kg, one to two times/day
SELECTIVE SEROTONIN REUPTAKE INHIBITORS		
Fluoxetine	1–3 mg/kg/day ^c	0.5–1.5 mg/kg/day
Fluvoxamine	1–2 mg/kg, one to two times/day	0.25–0.5 mg/kg/day
Paroxetine	0.5–2 mg/kg/day	0.25–1 mg/kg/day
Sertraline	1–3 mg/kg/day or divided bid	0.5–1.5 mg/kg/day
β-BLOCKER		
Propranolol	0.2–3 mg/kg, prn to bid	0.2–1 mg/kg, tid
α₂-AGONIST		
Clonidine	0.01–0.05 mg/kg, prn to bid	
AZAPIRONE		
Buspirone	0.5–2 mg/kg, one to three times/day	0.5–1 mg/kg, one to three times/day

TABLE 3 DRUG DOSAGES FOR BEHAVIORAL THERAPY
IN DOGS AND CATS (*continued*)

Drug	Dog Dosage	Cat Dosage
SEROTONIN ANTAGONIST REUPTAKE INHIBITOR		
Trazodone	3–8 mg/kg, prn to tid	
ANTICONVULSANTS		
Carbamazepine	4–8 mg/kg, bid-tid	2–6 mg/kg, one to two times/day
Gabapentin	5–30 mg/kg, bid-tid	3–10 mg/kg, bid-tid
Levetiracetam	20 mg/kg, tid	10–20 mg/kg, tid
Phenobarbital ^d	2–5 mg/kg, bid (to 10 mg/kg, prn for sedation)	1–3 mg/kg, bid
Potassium bromide ^d	10–40 mg/kg/day, or divided bid	Not recommended
GLIAL MODULATOR		
Propentofylline ^e	2.5–5 mg/kg, bid	
MONOAMINE OXIDASE INHIBITOR		
Selegiline ^{c,e}	0.5–1 mg/kg/day (in morning)	0.5–1 mg/kg/day (in morning)

^a prn = as needed^b Rare reports of hepatic necrosis with diazepam in cats and potentially with other benzodiazepines^c Licensed and labeled for veterinary behavior use in some countries^d Titrate upward if inadequate clinical improvement and serum levels not adequate^e Licensed and labeled for cognitive dysfunction in some countries

NORMAL SOCIAL BEHAVIOR AND BEHAVIORAL PROBLEMS OF DOMESTIC ANIMALS

HORSES

SOCIAL BEHAVIOR

Horses are social animals that under feral conditions (or on pasture) live in bands (harems) that consist of several mares, their offspring up to 2–3 yr of age, and at least 1 and as many as 6 adult males. The core of the group is the mares, which stay together

even if the stallion leaves or dies. The group size ranges from 2 to 21 horses; multiple-male bands are larger than single-male bands. Groups are not limited to a specific geographic area and will travel in search of resources. Colts and fillies leave the group usually before 2 yr of age (when they become sexually mature), stay alone for a few months, and then join a different group or establish a new one. Some colts may form a “bachelor band” with up to 16 males,

and later join other groups in which the stallion has died or been chased away.

Hierarchy in horses appears to be linear (with occasional triangular relationships) and not necessarily based on age, weight, height, gender, or time in the group. These are important factors when considering problems in stabled horses, and attentive management is required before introducing horses to each other. Offspring of high-ranking mares appear to be high-ranking later in life, which might indicate both genetic and experience components. Hierarchical rank in females is determined by observing group behavior (eg, seeking out resources such as water holes). Females make the decision about whether to leave or to stay within a band based on factors such as assessment of food resources or number of stallions in the group. High-ranking females can successfully interfere with the nursing of foals by lower-ranking females. Mares have preferred associates, are preferentially groomed, and will groom certain individuals. As in many other species, hierarchy in horses is based on deference by lower-ranking animals, not fighting.

The highest-ranking stallion in a band does most of the breeding, because it is the first to secure access to a receptive female and the first to displace a female from another band. In the absence of conception, horses cycle every 21 days during the spring and summer. There are three phases of sexual behavior in horses: courtship, mating, and postmating behavior. During courtship the stallion will approach the mare, prance, sniff her, nuzzle her, and groom her. The mare may squeal, kick, or move away to show the stallion she is not ready, or she may stand still, deviate her tail, and urinate, leading the stallion to mount her. Pasture breeding can achieve 100% success rates, versus 50%–60% for “in hand” or controlled breeding. This is probably because of familiarity between the horses, higher fertility of the mare, and less aggression between horses.

Ovulation usually occurs 36 hr before estrous behavior ends. Gestation lasts 315–365 days, with an average of 340 days. Factors that affect gestation length include nutrition, time of year (shorter time for late summer breeding), and gender (slightly longer for colts). Mares usually deliver at night, even when provided with artificial light. Bonding between mare and foal occurs in the first 24 hr. Most nursing behavior is initiated by the foal and terminated by the mare, especially in the first month.

During the first month of life, foals show maximal dependence on their dams and

have minimal contact with other horses. They spend most of the time resting near the dam. The socialization period is 2–3 mo of age; the foal starts playing with other foals and explores its environment. It is important to provide gentle handling during the first 42 days of life. At this time, snapping (teeth clapping) peaks. This is a behavior shown by foals toward adult horses, presumably to reduce aggression. It may also be a displacement nursing behavior, such as air nursing. Snapping is not the same behavior as smacking, which is an aggressive behavior or threat. Allogrooming also peaks at this time.

From 4 mo of age, the foal starts developing independent relationships and spends more time in adult maintenance behaviors such as grazing and resting while standing. There are sex differences in play; colts mount more and fight more than fillies, who focus on grooming and running. Colts groom only fillies, while fillies groom both sexes.

BEHAVIORAL PROBLEMS

Many behavioral problems are associated with confinement. Under free-ranging circumstances, horses wander and spend >60% of their day foraging. The remainder of their time is spent resting (standing or lying down), grooming, or engaging in another activity. This same pattern is seen under barn conditions; even with free choice of grain, horses will eat many small meals a day. Horses are highly social animals that require contact with others for normal daily maintenance and well-being. Isolating horses can lead to development of problems. The main goal of managing behavior problems in horses is to identify the deviation from normal equine behavior and correct it.

Aggression

Aggression is a common problem in horses and includes chasing, neck wrestling, kicks and bites, and other threats. Signs of aggression include ears flattened backward, retracted lips, rapid tail movements, snaking, pawing, head bowing, fecal pile display, snoring, squealing, levade (rearing with deeply flexed hindquarters), and threats to kick. Submissive horses respond by avoiding, lowering the neck and head, clamping the tail, and turning away from the aggressor.

Aggression to People: This behavior is seen mostly in stalls in which the horse feels confined in a small space that is also easily

defended. The varieties of aggression toward people include fear, pain induced, sexual (hormonal), learned, and dominance related. Some horses, especially young ones, play with each other while showing signs of aggression such as kicking and biting. Although benign to other horses, this can be dangerous to people.

The first step in managing equine aggression is identifying the cause, and if possible, removing it. Training and positive reinforcement to establish control over the horse are also used, along with desensitization and counterconditioning. Dominance-related aggression in horses is different from canine status-related aggression (also known as dominance aggression) in that it is not context-dependent. Environmental management is important as well; good management should include sufficient resources such as space, food, and water. Some horses are considered to have pathologic dominance aggression; they will attack other horses and people that are near them. These horses should be separated completely from other people or horses and have a poor prognosis.

Aggression Toward Other Horses:

Aggression toward other horses is mostly associated with sexual competition, fear, dominance, or territory (protecting the group and resources). As with aggression toward people, some horses may be pathologically aggressive toward other horses. The first step is separation of aggressive horses from other horses, and keeping subordinate away from dominant horses. Separation is achieved by solid walls or two fences to avoid kicks through the fence. Horses should have sufficient resources, and desensitization and counterconditioning is the best treatment approach. In cases of sexually related aggression, castration and progestins (eg, medroxyprogesterone 70–80 mg/300 kg/day) can help. Adverse effects of such treatment should be weighed carefully, and the horse should be monitored closely. Adding tryptophan to the daily ration or administering selective serotonin reuptake inhibitors (SSRIs) may be helpful in some cases. Punishment should be avoided.

Maternal Aggression: Aggression by mare toward people is normal during the first few days after parturition. This behavior is hormonally driven and usually wanes with time. Mares should be familiarized with their caretakers before delivery and have minimal contact with

other people after delivery. No treatment is required in most cases.

Aggression While Breeding: Stallions that are aggressive when used for breeding are often overused or used out of season. Stallions can develop preferences for mating and may not be compatible with the chosen mare; changing the mare may help. If stallions were stabled with mares when they were colts, they may have some social inhibition for mating, and forced mating can result in aggression. The goal of treatment is to treat the main cause of aggression; changing the mare (because of preferences) or artificial breeding can also be attempted. Physical restraint (eg, hobbles) and desensitization can help as well. Clicker training has been used successfully to desensitize stallions with this problem.

Stereotypic Behaviors

Compulsive behaviors in horses can be divided into movement-related behaviors and oral behaviors. They can be called stereotypic because they are repetitive, occupy a large part of the daily activity, and serve no function. Confinement and poor management practices are the primary contributing factors. In addition, bedding, feed, and social contact influence stereotypic behaviors. Horses that have more social contacts, are fed more roughage and more than one type, are fed two or more times daily, and are bedded on straw are less prone to these behaviors. Cribbing and wood chewing are examples of oral behaviors, whereas weaving, stall walking, and pawing are examples of locomotor stereotypies. Horses with one stereotypic behavior are likely to exhibit another. In Thoroughbreds, these behaviors are commonly seen in mares and 2-yr-old foals.

Cribbing (Aerophagia, Windsucking):

When cribbing, the horse usually grasps an object in the stall (such as the water bucket) with its incisors, flexes its neck, and sucks air into the pharynx. Some horses will aspirate or swallow the air. In some cases, horses will suck air without grasping any object. Feeding highly palatable food (eg, grains, molasses) is associated with cribbing. Lack of exercise is also associated with cribbing; endurance horses are less likely to do it than race or dressage horses. Thoroughbreds are more prone to cribbing than other horses. The rate of cribbing is higher in confined horses; however, even if the horse is turned to pasture once the behavior is

established, it will persist. It is possible that GI discomfort can lead to cribbing. One of the major complications of cribbing is damage to the incisors. Other problems include gastroduodenal ulcers and epiploic foramen entrapment. In most cases, cribbing is a benign behavior that does not affect the horse's welfare and does not require treatment. Close to 10% of foals 20 wk of age will start cribbing when weaned and placed in stalls. Those kept on pasture will not start. It has been speculated that horses can learn cribbing by watching other horses; however, no clear evidence exists.

Cribbing can be diagnosed by finding U-shaped pieces missing from fences and horizontal surfaces in the stall, and worn incisors and enlarged neck muscles in horses that crib. In some cases, the caretaker may directly observe the behavior. Management should include more roughage, exercise, and social contact. Turning confined horses to pasture may help, and providing toys and stimulation is also advocated. Placing a strap around the horse's neck behind the poll will apply pressure each time the horse tries to flex its neck. This essentially punishes the horse for cribbing, with the punishment associated with the behavior and not the caretaker. Alternatively, an open-end muzzle can be applied. This will allow the horse to eat and drink but prevent it from grasping objects to crib on. Some horses find a way to crib with the muzzle (eg, grasping a linear object, such as a stick), and most horses seem to tolerate the strap better than the muzzle. Keeping stalls free of horizontal surfaces and objects that the horse can grasp can help minimize cribbing. A variety of surgeries have been suggested to manage cribbing; however, the varying success rates and negative impact on animal welfare are significant disadvantages.

Wood Chewing (Lignophagia): Like a horse that cribs, a wood-chewing horse will grasp pieces of wood with its incisors, but unlike in cribbing, it will swallow the pieces. The definitive cause of wood chewing is lack of roughage in the diet. Confinement, high-concentrate diets, and lack of exercise and stimulation increase incidence of wood chewing. Horses on pasture normally spend 8–12 hr/day grazing, while confined horses spend <3–4 hr/day feeding. Wood chewing increases in cold, wet weather. Providing more roughage, exercise, stimulation, toys, or social contact can reduce incidence of this behavior. Eliminating exposed wood

and covering fence edges with wires and taste repellents can also help minimize wood chewing.

Geophagia (Pica): Most horses will ingest sand or dirt. Soil that is ingested is richer in iron and copper than other soils, and this may attract the horse. Ingestion of stones can become a serious problem, because it can lead to intestinal obstructions. Management should include increasing roughage and exercise and providing salt blocks and toys.

Polydipsia: Polydipsia in horses is similar to behavior seen in dogs (*see* p 1568). The most common presenting complaint is a wet stall due to frequent urination. It is important to exclude medical causes (eg, diabetes insipidus).

Stall Walking and Weaving: These behaviors are seen in confined horses, serve no purpose, are hard to interrupt, and are usually slower than other types of movement. Horses that stall walk usually walk in circles in the stall, and when released to a larger space (eg, pasture or barn) continue to circle in a small area. Tying the horse to prevent walking will only transform the behavior into weaving, ie, lifting the legs and shifting weight and head position from side to side in the same spot. Possible causes of stall walking include lack of exercise and social contact and claustrophobia. Stress and anxiety appear to aggravate the problem. Treatment should focus on increasing exercise and stimulation, providing social contact, and turning the horse to pasture. Providing thick bedding and feeding more than twice daily can help as well. In extreme cases, SSRIs might be necessary to control the problem. Providing a large mirror in the stall in front of the horse can help decrease weaving.

Stall Kicking: Horses may kick the walls of the stall because of boredom, aggression, or frustration. The horse may kick in anticipation when food is being prepared but is out of reach. When the horse is then fed, the behavior is reinforced. The horse may also be frustrated when it cannot achieve its goals (eg, exercise, mating, or social contact). It is possible that this behavior is a form of self-mutilation. Many horses that kick and make holes in the walls of the stall also eat wood from these holes. Treatment should be directed toward eliminating the underlying cause. Treatment for aggressive kicking is discussed

earlier (*see* p 1546), and for most other causes the treatment is similar to that for stall walking (*see* above). Owners should never reinforce kicking by providing food when the horse kicks. Providing more social contact, exercise, and stimulation can also help.

Pawing: Similar to kicking but less dangerous, pawing or digging may be a result of frustration and anticipation. This could also be a displacement behavior. Changing the floors to concrete may stop pawing; however, it will not change the motivation to do so, and some horses (especially stallions) may rear up instead of pawing. Treatment is similar to that for kicking (*see* above).

Head Shaking: A head-shaking horse shakes or jerks its head uncontrollably, without any apparent stimulus. Some horses will also snort, rub their head on objects, and display an anxious expression. Most commonly, horses shake up and down. There are five grades to this problem: 1) intermittent signs, mainly facial twitching; 2) moderate signs with noticeable shaking such that can interfere with riding; 3) advanced stage, and difficult to control; 4) uncontrollable and unrideable horse; and 5) dangerous behavior with bizarre patterns. In most cases, the horse looks as if it has nasal mites or is being attacked by biting flies. Many medical conditions can cause head shaking (eg, seizures, respiratory tract diseases and parasites, ear and eye disease, GI disorders, pain, trauma, nasal foreign bodies), and these must be excluded. Behavioral causes of head shaking include an improper bit, an incompetent rider, fear and anxiety, dressage leading to extreme cervical flexion, and compulsive disorders. Geldings seem to be affected more frequently than stallions or mares. Management should include treating any underlying medical problem, desensitization and counterconditioning, and potentially use of SSRIs.

Self-mutilation: Some horses hurt themselves by biting or kicking the abdomen with their hindlegs. Some of these horses also vocalize. Underlying causes include displacement behavior, self-reinforced behavior, and redirected behavior. Skin diseases and pain can also lead to self-mutilation and must be excluded. This problem seems more common in young males (<2 yr old) and may possibly be triggered by environmental stressors. Management should include sufficient

stimulation and exercise and increased social contact.

Fear and Phobia

Like dogs, horses can have fears and phobias. The two main presentations are noise and location or environment phobias. Horses have an innate fear of new things (neophobia) that explains some behavior issues such as trailer-related problems (*see* below). The management is similar to that in dogs and cats (*see* p 1565).

Trailer-related Problems: There are two main presentations of trailer-related problems: loading into the trailer and travelling. Horses may be afraid to load into a trailer because of innate factors (eg, neophobia, a dark interior, instability of the trailer, noise) and/or learned factors (eg, previous accident, motion sickness, previous punishment while loading). A horse may load into a trailer readily but misbehave while inside. This could be because the horse finds it difficult to keep its balance while the trailer is moving, anticipates a stressful event such as a race after the trailer ride, or has motion sickness. In a small number of cases, horses are reluctant to leave the trailer. Heart rate and salivary cortisol levels have been shown to increase during and after trailering.

The best approach to managing trailering problems is slow desensitization and counterconditioning using food and treats. This may take a long time and may not be suitable for an acute problem. Desensitization should be done long before the expected trailer ride. Punishment should be avoided, because it may aggravate the situation and be dangerous for both the horse and the caretaker. Some horses prefer to see their environment and may load better in a rear-facing trailer. Horses are herd animals and learn from each other; having a horse with a trailer-related problem view another horse loading can facilitate learning. Foals should be loaded with their mothers at an early age. Sedatives such as xylazine can be used in acute situations; however, the horse may not learn to load or ride better while drugged and may be less able to balance itself for the ride and any performance after the ride.

Sexual Behavioral Problems

Silent Heat: Behavioral anestrus is a common problem in young mares, especially during the first cycle. The ovaries are normal on palpation, and ovulation

occurs normally. However, the mare will not accept the stallion. Causes include environmental stressors and mating preference. Presenting several stallions may help, and if the mare is still nursing a foal, weaning may help.

Nymphomania: Medical conditions that can cause excessive sexual behavior in mares include granulosa cell tumor and persistent ovarian follicles. These conditions should be differentiated because a persistent follicle may resolve without treatment (although it may require treatment with gonadotropins or luteinizing hormone or increasing daylight to ≥ 16 hr), whereas granulosa cell tumors require surgical resection. Excessive estrous behavior is manifested as squatting and urinating frequently, receptiveness to males, and exposing the clitoris ("winking"). Some granulosa cell tumors produce testosterone, leading to stallion-like behavior (eg, aggression, mounting, flehmen, and urine marking). Management should be directed toward the underlying problem.

Psychic Estrus: Mares with psychic estrus show estrous behavior without any of the physiologic correlates of heat. Treatment is as for nymphomania (see above).

Poor Libido: Overused stallions, submissive stallions presented to aggressive mares, and stallions with previous negative experiences may be unwilling to mate. Masturbation is a normal behavior in horses; colts will start mounting within the first few weeks of their lives. Ejaculation is rare, and fertility rates are unaffected. Some owners use various devices to stop masturbation; these essentially punish the horse for masturbating and cause pain. They can cause fear while trying to breed and predispose the stallion to poor libido. Management should be directed toward eliminating the underlying problems. The stallion should be presented with teaser mares, should be well rested and fed, and have increased social contact with mares on pasture. Using an artificial vagina to desensitize the stallion can help, and treatment with anxiolytics such as diazepam may address underlying anxiety. Other cases may require semen collection and artificial insemination.

Stallion-like Behavior in Geldings:

Approximately 50% of geldings show some stallion-like behavior, including courting and mounting females, flehmen, fighting, and attacking foals. The brain of the male

horse is masculinized before birth; therefore, some of these behaviors do not require androgens to be expressed. Some geldings may achieve erection and intromission while mounting the mare. In advanced cases, the horse should be checked for pituitary adenoma. Normally, the testosterone level should be <0.2 ng/mL. Treatment includes separation, progestins, and SSRIs.

Eating Disorders

Coprophagia: Eating feces is mainly seen in foals during the first 8 wk of life. Foals usually consume fresh feces of their mothers, and it is believed that maternal pheromones play a role in this behavior. Deoxycholic acid is found in feces and may help protect against infantile enteritis and aid in deposition of myelin. The behavior may also provide vitamin B and introduce normal intestinal flora. In adults, the behavior is mainly associated with a low-roughage diet.

Obesity: Decreased exercise and overfeeding a palatable and highly concentrated diet can lead to obesity. On pasture, horses spend 8–12 hr grazing while moving from place to place; confined horses spend <3 –4 hr. Increasing exercise, social contact, and roughage can help maintain appropriate body weight.

Anorexia: Horses are herd animals, and any changes in social relationships or the environment can increase stress and lead to anorexia. Appropriate weaning of foals is also important to prevent anorexia. Submissive horses may not eat near aggressive horses if they have previously been attacked. Management should be directed toward the underlying problem. Increasing social contact and separating affected animals from aggressive horses can help.

Foal Rejection

There are three types of foal rejection: 1) avoidance, seen mainly in primiparous mares that appear fearful of the foal—the mare will not attack the foal but will not allow suckling; 2) intolerance of suckling, which is seen in primiparous mares or mares with a painful udder; and 3) aggression toward the foal, in which mares exhibit stallion-like behavior and may kick and bite the foal. There may be a genetic factor for this type of aggression in Arabians and Morgans. Some mares paw at the foal to stimulate them to stand, and this should be differentiated from aggression.

The most important aspect of treatment is to protect the foal. In extreme cases, the foal should be supplied with colostrum within the first 12 hr and then bottle fed or cross-nursed to another mare. Restraining a primiparous mare and letting the foal suckle may teach the mare that nursing is pleasurable and encourage her to let the foal nurse without restraint. Avoiding any disturbances while the mare is nursing the foal is paramount for successful nursing. Any evidence of mastitis or retained placenta should be addressed. For an aggressive mare, appropriate restraints such as a barrier or tying should be considered. Feeding the mare treats while the foal nurses can help desensitize her. In some cases, stimulating maternal behavior by separating the mare from the foal or faking a threat to the foal (eg, other horses, dogs) can help. Medications such as acepromazine, xylazine, diazepam, and progestins may help; however, these drugs can enter the milk and affect the foal.

CATTLE

SOCIAL BEHAVIOR

Range cattle live in groups of cows and calves; males are often separated until breeding season. Dominance in cattle is based on age, sex, weight, presence of horns, and territoriality. Breed also seems to play a role—heavier dairy cattle are dominant to lighter breeds, while lighter beef cattle are dominant to heavier breeds. When a heavier and older cow is introduced into a group, it is usually subordinate to existing members of the group. In large herds, triangular relationships between cows exist. In dairy cattle, hierarchies change constantly as cows are added or removed from the herd. Once a hierarchy is established, overt aggression is reduced.

Very little is known about vocal communication of cattle; most commonly noted are the moo, call, hoot, and roar. A distressed cow or calf will call or hoot, an aggressive bull may roar, and a hungry calf will give a high-intensity “menh.”

Under natural conditions, cows cycle throughout the year, with peak activity between May and July and low activity between December and February (northern hemisphere). The heat cycle is usually 18–24 hr and generally begins in the evening. Common estrous behaviors include reduced food intake, increased movement, flehmen, standing behind another cow and resting the chin on its back, and increased licking

and sniffing. Aggression and mounting also increase during the cycle. Heat detection is an important practice, especially in dairy cattle, in which artificial insemination is common. There are many methods to augment the detection of heat, including placement of dyes on cows' backs that will stain the estrous cow's ventral torso and pedometers that record increased movement. On some farms, a teaser bull is still in use. Bulls on pasture will graze alongside proestrous cows; the bull will stand head to head with the cow or may rest his head on her back. As estrus progresses he will try to mount, licking her vulva and showing flehmen.

Parturition normally occurs at night on pasture, and the calf normally starts suckling in <3 hr. The newborn calf spends most of its time near the dam until it is ~4–6 mo old, when it forms unstable groups with other calves. Cows maintain bonds with their calves even when the next calf is born. On pasture, heifers are weaned when ~8 mo old and bull calves when ~11 mo old. Social status increases with age, and social relationships are not stable until at least 1 yr of age.

BEHAVIORAL PROBLEMS

Most behavioral problems in cattle involve breeding or aggression and are related to poor management practices, confinement, and lack of enrichment.

Breeding-related Problems

Silent Heat: Silent heat occurs most often in heifers during the first cycle. Physical signs of heat (eg, vaginal discharge, vulvar relaxation, and behavioral signs) are absent. Estrus detection methods (*see above*) can help identify cows in heat. In recent years, the use of freemartins and dogs for detection of estrus has gained popularity.

Nymphomania: Increased sexual behavior occurs mainly in high-producing dairy cows that are 4–6 yr old and have had 1–3 calves. These cows usually mount other cows excessively, act like bulls, and have a significant decrease in milk production. In most cases nymphomania is associated with follicular cysts, and treatment with luteinizing hormone or chorionic gonadotropin is useful.

Masturbation: Masturbation in bulls normally does not affect fertility. The bull will have a partial erection, arch its back, and perform pelvic thrusts. Because this does not lead to increased aggression or

reduced fertility, no treatment is needed. Increases in exercise and stimulation can reduce the frequency.

Poor Libido: Many diseases of bulls can lead to poor libido; therefore, the first step in managing impotence is excluding and treating possible diseases. Bulls with poor libido may refuse to mount, avoid estrous cows, and be unable to develop an erection. Behavioral causes for impotence include inexperience in young bulls that attempt breeding an aggressive cow, bulls that are used too frequently for semen collection, and the stress of a new environment. Using a new teaser bull or, preferably, a teaser cow in estrus can stimulate these bulls to breed. Allowing the bull to watch other bulls mounting may increase arousal. Food rewards (eg, molasses) may help as well. In many cases impotent bulls should be eliminated from breeding programs, or alternative ways of semen collection such as electroejaculation should be used.

Buller Steer: Buller steers are steers mounted by others. This problem is seen in ~3% of feedlot steers and seems related to both hormonal and crowding factors. Steers are usually implanted with anabolic steroids, most commonly stilbesterol or estrogen, which can lead them to mount others. However, the level of these hormones in the buller is usually lower. In large, overcrowded groups of steers, the number of bullers is higher. This problem may also be related to dominance; the more dominant and aggressive steers mount others. Erection and intromission rarely occur. Both the buller and the mounting steer may fail to gain adequate weight because of psychological stress and increased activity. Removing the buller is the most common solution. Adding hiding places, placing overhead electric wires, providing sufficient food and water to avoid conflict, and painting odiferous material on the back of the buller also can help reduce incidence of this behavior.

Aggression

Aggression in cattle is usually a result of fear, learning, and hormonal state. Aggression between cows is worse than that between bulls. Horned cattle will bunt (push or strike with the horns) and strike an opponent on the side. Polled cows will use their head as a battering ram. Two cows can fight for a long period with resting periods in between. Each cow will rest while pushing its muzzle between the udder and hindquarter of the other cow to immobilize it.

Aggression toward people usually includes bunting, kicking, and crushing. Aggressive and dangerous animals should be culled.

Aggression in Bulls: Bulls are notorious for their unpredictable aggression. Some bulls may mount others, and these may respond with aggression. Such fights can end with serious injuries and even death, especially if the bulls are horned. Dairy bulls are commonly more aggressive (and also larger and heavier) than beef bulls. The bull may paw and dig in the ground, and horned bulls may kneel on the front legs and dig using their horns. Because hand-reared bulls are more aggressive toward other bulls, it is thought that inadequate socialization may contribute to this behavior. Aggressive bulls should be separated from others and perhaps culled if dangerous to people.

Kicking: Kicking is mainly a problem in beef cattle and is seen most commonly in heifers. Beef cattle are not selectively bred for gentleness and are handled minimally. These animals can be dangerous when placed in pens or cages for examination and may cause severe injuries. Such animals should be handled carefully and potentially sedated. Food rewards can be offered for calm behaviors.

Nursing-related Behaviors

Intersuckling: Non-nutritional suckling is a common problem in calves; the suckling calf will suck on other calves or the cow on any available appendage or skin tag. This can lead to skin irritation and even umbilical hernias (if the suckling calf suckles on the umbilical sheath of another calf). Poor nutrition may influence development of this behavior (increasing roughage can minimize the problem). Penning or isolating suckling calves does not solve the problem; the calf will continue to suckle on buckets or engage in self-suckling. The problem is more common in calves weaned after 6 days of age. Non-nutritional suckling occurs mostly after feeding; providing dry teats next to the feeding area can help reduce incidence of this behavior. Other ways to minimize this behavior include placing a serrated nose ring in the suckling calf, applying repellent materials to suckled areas, and fitting a muzzle. These may prevent suckling but do not reduce the motivation to do so, and calf welfare should be considered.

Cross-fostering: In some cases, it is necessary to cross-foster a calf. Dairy cows are more likely to refuse a new or unfamiliar

calf than beef cows. Bonding between the cow and calf is based on fetal fluid and visual cues; therefore, covering the new calf with drapes soaked with anesthetic fluid or the skin of the cow's own dead calf or blindfolding the cow can help. Encouraging the cow with food rewards can also help.

Miscellaneous Behavior Problems

Reluctance to Enter the Milking Parlor

Parlor: Reluctance to enter the milking parlor is a problem related mainly to management. When dairy cows accustomed to milking with simultaneous feeding in a stanchion barn are moved to free stalls and are not fed when milked, they may refuse to enter the parlor. Previous negative experience (eg, mastitis, aberrant electric shock, punishment from the handler) can also play a role. In addition, changing the side from which the cow is normally milked can increase anxiety and even aggression. Providing more grain feeding, a calm environment, and possibly a preferred cow "mate" can help minimize the problem. Similar problems can arise with the introduction of electric squeeze gates.

Food Throwing: The underlying cause of food throwing is not well understood. The affected animal grabs food with its mouth and throws it on its back. One possible explanation is maintenance behavior that is meant to reduce biting flies in the presence of docked tails. The diet mixture may also play a role; the problem is seen more commonly in cattle fed a total mixed ration.

Tongue Rolling: Tongue rolling occurs mainly in veal cattle and is most likely a stereotypic behavior resulting from confinement. The affected calf flicks its tongue outside and rolls it back inside the mouth, followed by swallowing saliva. One study showed that veal calves that displayed tongue rolling had no abomasal ulcers, while those that did not show this behavior had ulcers. This may indicate that the behavior reduces stress. However, calves that showed tongue rolling as well as those that did not had abomasal erosions. Increasing stimulation (eg, adding sucking teats) may reduce incidence of this behavior.

typically consist of three sows and their offspring. Boars are solitary. A hierarchy is formed at social maturity. Sows in the same group cycle at the same time and participate equally in group maternal behavior; one sow will remain with the piglets while the others forage. Communal nesting is also found under free-ranging conditions. In confined pigs, a hierarchy is formed as early as 1 wk of age. Piglets will fight newly introduced piglets in the pen. Piglets also form a teat rank by the end of the first week of life; the dominant piglet suckles on the first pair of teats and gains weight faster. Once the teat order is formed, the hierarchy remains stable as long as the same piglets remain in the same group. Normally, the heavier pig is more dominant. It appears that both genetics and experience play a role; dominant sows give birth to dominant piglets. Once a hierarchy is formed, fighting is mostly replaced with threats. Weaning takes place within the first 3–4 mo of the piglet's life, but in mass production environments, it can take place as early as 3–4 wk of age.

Sows normally have two estrous cycles per year and farrow twice. Pheromones and the sight of a boar are major factors in inducing cycles in gilts. In postfarrowing sows, weaning helps induce estrus; boars can be used to detect females in heat. The boar is usually highly vocal (courting song) and exhibits flehmen when an estrous female is present. Boars will nuzzle the head, shoulders, flank, and anogenital area of sows during courtship. Normally, boars urinate several times and produce thick saliva rich in pheromones. Boars raised without the presence of other pigs show low sexual performance.

Communication in pigs is mainly vocal; there are ~20 different recognized sounds. The grunt is one of the most common sounds, given in response to familiar sounds or while looking for food (rooting). A short grunt is given when the pig is excited, whereas a long grunt is a contact call and normally associated with pleasurable stimuli. When pigs are aroused they may squeal, and they may scream when hurt. Dominant pigs bark at subordinate pigs as a threat. Visual signals in pigs are not well developed. The tail position indicates the well-being of the pig. A tightly curled tail is an indication of a healthy pig, and a twitching tail indicates skin irritation. In mass production environments, tails are normally clipped to avoid tail biting (see below). Olfactory signals are highly developed in pigs. There are sex differences; sows can detect lower concentrations of

SWINE

SOCIAL BEHAVIOR

Pigs are social animals that under free-ranging conditions live in groups of approximately eight individuals. The groups

smell and pheromones than boars. When introducing a new pig into an existing group, the resident pigs investigate the newcomer by nosing it. Pigs can form social ranks when they are blindfolded, which indicates the importance of olfactory and vocal communication.

Socialization in piglets starts at ~5 wk of age with conspecifics and at 14 wk of age with other species. Pigs 14–17 wk old are most sensitive, and any negative or unpleasant experience during this period can delay sexual maturity, leading to late first farrowing. In free-ranging conditions, grouping promotes foraging, nursing, and protection against predators. Pigs under free-range conditions will also choose one place to defecate. In commercial production, the most noticeable group behavior is in newborn piglets, which huddle when cold.

BEHAVIORAL PROBLEMS

Many behavioral problems in swine are related to confinement or stress. The treatment is usually directed toward managing social groups, establishing normal conditions when possible, and maintaining welfare.

Aggression

Aggression Toward Other Pigs: Piglets show aggression to other piglets within the first week of life while forming a teat order. Later, introducing new pigs into a group may lead to aggression as the pigs establish social ranks. Pigs may spend 1–2 min nosing each other, vocalizing, and then biting until one of the pigs retreats. It may take several days to establish a hierarchy in older pigs. Once the hierarchy is established, fights are rare and ranks are preserved mostly by threats from the dominant pig and submissive gestures from subordinates (eg, twisting the head away). During estrous cycles, sows may show severe aggression toward newly added sows. Submissive sows show the least estrous behavior, have small litters, and lose weight (most likely due to low nourishment). Most aggression in pigs seems to be related to resources such as food. Crowding and limited amounts of food increase aggression. During breeding, boars may fight and become very vocal; boars will strut shoulder to shoulder, champ their jaws (producing pheromone-rich saliva), then finally face each other and attack. Serious injuries may result, especially among boars that still have their tusks. Breed likely plays a role; Large Whites are more aggressive than Hampshires, which are more aggres-

sive than Durocs. Body fat percentage may also be a factor; breeds with lower body fat are more aggressive when handled.

Management includes slow introduction of new pigs into existing groups, provision of shelters where subordinate pigs can hide, provision of sufficient resources and toys, and application of boar pheromones. Most producers keep lights dim in the pen to reduce aggression. Using tranquilizers such as azaperone (2.2 mg/kg) or amperozide (1 mg/kg) can help reduce aggression but may not be economical. Lithium (an antipsychotic) has been used successfully.

Tail Biting: Tail biting is seen mostly in confined pigs. Overcrowding and boredom seem to be the main causes. Free-ranging pigs spend 5–10 hr daily looking for food and rooting, whereas pigs kept in pens consume meals in a short time. Slatted floors without bedding, low-salt diets, and low-iron soil seem to predispose pigs to tail biting. Once the problem starts, blood from the injured tail seems to arouse the other pigs and can even lead to death of the victim but rarely advances to pure cannibalism. Most losses are due to secondary infections that result in culling. Management includes removing the biting pigs (if there are only a few of them) and providing stimulation such as straw bedding to root, toys, and corn on the cob to chew. Most commercial producers dock piglets' tails; however, this does not reduce the motivation for tail biting, and pigs may bite the stump or ears instead.

Cannibalism: Mostly seen in primiparous gilts, cannibalism accounts for 4% of piglet deaths and is estimated to affect ~18% of litters. It is most common immediately after parturition when the sow is stressed. Usually, the sow will bark to warn piglets walking by her head and then later attack them, biting them to death. Farrowing crates have been used successfully to reduce the incidence of cannibalism. Azaperone (2.2 mg/kg) has been used for treatment as well.

Crushing Piglets: Heavy sows may lie on their piglets, killing them. This normally occurs when there are weak, underdeveloped, or sick piglets that cannot move fast enough to avoid the sow. However, it is also a breeding and management problem—sows are naturally intensely protective mothers that will prevent the handler from attending to the piglets; selective breeding for less-protective sows has resulted in sows less devoted maternally. Management includes providing appropriate farrowing crates with slopes and bars on the sides that

allow the piglets to move away from the sow and prevent the sow from rolling over on the piglets. In addition, heat lamps provide the piglets with an alternative heat source and motivation to rest away from the sow.

Breeding-related Problems

Reproductive problems are usually associated with management of boars and sows and estrus synchronization. These problems are fairly unusual in pigs because of rigid genetic control of sexual behaviors. Mating preferences are an important factor in breeding management of pigs.

Poor Libido: Poor libido in boars can be caused by nutritional problems (deficiencies or overfeeding) and behavioral causes such as stress or fear. Exposing a boar to an aggressive female can result in low sex drive. Socialization, visual social contact with affiliative sows for a few days (in pens across from each other, not next to each other), and appropriate nutrition are the keys to successful management.

Failure to Reproduce: This is seen mainly in confined gilts, and stress seems to play an important role. Regrouping or overcrowding increases stress levels as well. These two factors (confinement and crowding) lead to chronic stress, delayed puberty, and failure to reproduce. In contrast, acute and mild stress such as transport and gentle handling accelerate estrous cycles.

Refusal to Nurse: Normally, the sow lies in lateral recumbency and grunts to attract the piglets to nurse. Mastitis is the most common reason sows refuse to nurse piglets. A physical examination is necessary to exclude this and other medical conditions. The sow lies sternally, preventing the piglets from accessing the teats. Mastitis is typically seen during late phases of lactation when the farrowing crates are removed. Sows with postpartum dysgalactia syndrome and mastitis (see p 1373) are usually too weak to move and prevent the piglets from nursing. However, these sows usually do not eat, and their piglets do not gain weight. Piglets of such sows should be transitioned to milk replacers and solid food. This can be encouraged by mixing sow's milk with the food or sweetening the food.

Stereotypic Behaviors

Stereotypic behaviors are not common in pigs and mostly relate to management, boredom, and nutrition. The most common

stereotypic behaviors include rubbing nasal secretions on the floor or another pig, bar biting by confined sows, and polydipsia. Environmental enrichment in early stages is usually successful. Feeding smaller quantities more frequently and providing toys, bedding to root, corn on the cob, and clean tires can be enriching and mentally stimulating for pigs.

SHEEP

SOCIAL BEHAVIOR

Sheep are a prey species, and their only defense is to flee. Sheep display an intensely gregarious social instinct that allows them to bond closely to other sheep and preferentially to related flock members. Flock mentality movements protect individuals from predators. Flocks include multiple females, offspring, and one or more males. Ewes tend to stay in their maternal groups for life, whereas rams may form transient, unstable, and easily disbanded bachelor herds. If most rams in a group die because of fights or diseases, those remaining join another group. Under standard grazing situations, sheep graze together in casual affiliations; social hierarchies are not as apparent as they are for cattle.

Flock dynamics are apparent in groups of four or more as evidenced by willingness to follow a leader or flee in unison. When escape is prevented, even a ewe may charge or threaten by hoof stomping. Separation from the flock can cause stress and panic. Isolation from other sheep can cause severe stress and should be avoided. Mirrors can be used in the absence of other sheep.

Males in rut will physically challenge one another for social rank and breeding privileges. Social rank depends on the presence and size of horns, body mass, and height at the withers and hocks. Age may also play a role, because the mortality of lambs from yearling ewes is extremely high. Higher-ranking males concentrate on courting females when in rut and do not graze to the extent lower-ranking rams do. Groups of 40–50 ewes/adult ram and 25–30 ewes/juvenile ram are common management choices. Mortality in rams is five times that in ewes. Generally, subordinates and lower-ranking rams are excluded from breeding, unless lower-ranking animals outnumber the higher-ranking male and serve to distract or otherwise occupy him (this need not be cooperative). While the higher-ranking male usually has larger

horns, the role of the demographic environment (ie, the number of lower-ranking males in the group) prevents an extreme selection response for these secondary sex characteristics.

In large groups of sheep or in sheep on large pastures, more subordinates are likely to mate. In tightly confined, relatively small groups, the role the social order plays in mating is critical, and owners should understand that lower-ranking rams may not mate under such conditions.

Sheep are seasonally polyestrous and reach puberty at 7–12 mo. Mating behavior includes nudging, kicking, or pawing with the front legs, low stretching, and pushing. These same behaviors and head-to-head banging with horn clashing occur in conflicts between males.

Artificial weaning occurs at 10 wk of age, but these lambs recognize and will return to the ewes after a 2-mo separation. Sheep are naturally weaned at 6 mo of age, usually when their mother again comes into heat. Ewe lambs continue to follow the dam, but ram lambs do not.

Sheep are likely to be more intelligent than generally regarded. They respond readily to food calls, may problem solve, learn their names, carry packs, and can even be clicker trained. Sheep may be grazed on open, unfenced areas and may heft (remain in home field) to a limited area as a learned behavior by lambs from their ewes. Sheep possess specialized neural mechanisms in the right temporal and frontal lobes of the brain and may recognize familiar human or ovine faces for as long as 2 yr.

BEHAVIORAL PROBLEMS

Homosexuality: Homosexuality is a normal behavior in sheep and is seen in up to 30% of all rams. Incidence of homosexuality is decreased in rams raised in heterosexual groups and in rams that have experience with ewes, but it still persists. It is unclear to what extent such behaviors are facilitated by a sex ratio that has been skewed for mating purposes.

Lamb Stealing: Ewes can steal the lambs of others before their own parturition and then reject their own lamb when it is born. Lambs seek out soft, warm, hairless areas (regardless of where they are), which can help with raising orphaned lambs but render stealing easier. Individual pens or partial barriers can usually prevent theft. Ewes will sequester the lambs at first, and providing them a shelter where this can be done will help. The smell of the wool is important to

the ewe for individual lamb recognition, as is the shape and color of the lamb's head. Ewes are more likely to accept lambs that have familiar head coloration.

Lamb Rejection: Lamb rejection can be associated with the social hierarchy or due to behavioral, physiologic, or environmental stresses (eg, rain) at delivery. The smell of the wool is important to the ewe, and lambs that smell unfamiliar are more likely to be rejected. Experimental results show that lambs whose heads have been altered are at risk of rejection. Alteration of the tail does not have the same effect. If the rejection is noted sufficiently early, using a stanchion to confine the ewe with the lamb can address the problem. Tranquilization may be needed.

Cross-fostering: Cross-fostering can be a successful solution for abandoned, rejected, or orphaned lambs. Cross-fostering is best addressed by fooling the ewe, using cervical stimulation (using balloons that stimulate oxytocin release and maternal behavior). Covering the lamb to be fostered with a t-shirt that the ewe's own lamb has worn can provide an appropriate olfactory cue, as can the skin of the ewe's own dead lamb.

Stereotypic Behaviors: In sheep, stereotypic behaviors include wool-sucking, intersucking, and self-sucking (tails or udder).

GOATS

SOCIAL BEHAVIOR

Social behavior in goats is similar to that in sheep, and horns also play a major factor in caprine social rankings. Goats also hide early in life but, unlike cows, spend more time away from the nannies for the first 6 wk than for the next 6 wk. The nanny initiates early approaches, and the kid initiates the later ones. Sexual behavior of goats differs slightly from that of sheep. Billy goats throw their head up in the air and ventroflex their neck when they ejaculate. They also frequently urinate on their front legs, which they then rub on the doe as part of the courtship ritual. The scent of female urine is important and is transported into the vomeronasal organ during flehmen.

BEHAVIORAL PROBLEMS

Behavioral problems are not commonly reported in goats, perhaps because adult

males are expected to charge people if their turf is traversed. Behavioral problems may actually be more rare (as opposed to less frequently reported) in this group, because their maintenance conditions more closely mimic those in a free-ranging situation. Domestication may have had less of an impact on the social patterns of goats than is true for other species.

Self-suckling: Goats that abort late in pregnancy or those that have a second pregnancy subsequent to nursing can self-suckle. The latter situation may be illuminating, because the behavior did not occur when the nanny was nursing. Treatment involves behavioral and environmental enrichment, social companionship that is stable before pregnancy, and possibly some antianxiety medications.

Stereotypic Behaviors: Stereotypic behaviors in goats are similar to those in sheep (*see above*). Goats separated from a group may develop competitive “rearing” or elevation.

CHICKENS

SOCIAL BEHAVIOR

Free-ranging chickens are social animals. In these groups, hens and chicks are the core, while roosters live independently. Social maturity occurs at ~1 yr of age, although most chickens are sent to slaughter before this age. Free-ranging chickens show more aggressive behaviors than battery chickens do. Rank is based on multiple factors (eg, size, age, color, and social environment). A new or foreign chicken is lower in rank than a chicken on home ground. Both nesting and food intake are genetically controlled behaviors, and chickens are selected for high food intake. Hens will form nests if supplied with nesting material. An adult chicken that has never used a nesting box will use one if provided.

BEHAVIORAL PROBLEMS

Aggression and feather pecking or plucking are the two most common behavioral problems in chickens. They may be related and possibly have similar underlying components, including stress, overcrowding, and competition over resources such as food. Both conditions can be managed by addressing the underlying problem and in

some cases by removing the instigator. Providing enrichment and changing the social structure by removing or adding individuals may help as well. In rare cases, aggression can advance to cannibalism (*see p 2873*). Broilers and free-ranging chickens are more likely to show these problems because egg-laying chickens in mass production are usually confined to small groups.

Aggression can manifest as pecking at the head and face or as pecking at and pulling feathers. Chickens have sharp and strong beaks that may lead to severe injuries. Reducing daylight in battery conditions, adding tryptophan to the food, and beak trimming can minimize aggression. Beak trimming is a symptomatic treatment, however, and may raise welfare concerns.

Grooming and feather care are part of normal hygiene in chickens and can also be social activities. Dust baths can help reduce the incidence of feather picking.

DOGS

SOCIAL BEHAVIOR

The dog's social structure has been referred to as a pack hierarchy, but this does not accurately or entirely describe the relationship of dogs with other dogs or with people.

Scientific studies into the behavior of wild wolves have established that the wolf pack is actually a family unit, with the adult parents guiding the activities of the group. The dog likely originated from the grey wolf 12,000–14,000 yr ago, although the origins of domestication may extend back 30,000 yr. Communication and relationships are established through a language of visual signals (body postures, facial expressions, tail and ear carriage, and piloerection), vocalization, scents, and pheromones. However, domestication and selective breeding have led to extensive variation not only from wolf to dog but also between breeds and individuals in morphology, breed traits, temperament, behavior problems, variation in behavioral neoteny, and social signaling. In fact, Huskies retain most of the social signaling repertoire of wolves, German Shepherds less than ⅓, and Cavalier King Charles Spaniels the least. Thus, it may be difficult for dogs (and people) to read and interpret the signals of other dogs, especially those of different breeds. Early and frequent socialization with a wide variety of dogs is therefore an important component of intraspecific communication.

The term dominance (*see p 1536*) does not describe the relationship between two

individuals; it is a relative term established by the value of the resource to each individual and the cumulative effects of learning.

Hierarchy in dogs is neither static nor linear, because the motivation to obtain and retain a specific resource, together with previous learning, defines the relationship between two individuals for each encounter. Stability is maintained by deference and not by agonistic behaviors. Only in those relationships in which one individual consistently defers to another across resources and interactions might a linear hierarchical relationship between the individuals be described. Although this terminology applies to the intraspecific communication and signaling between members of a species (eg, dog-dog), it does not "translate" to communication between species (eg, dogs-people).

Relationships with people are not established by dominant/submissive social signaling; they are a result of genetics, early handling, and socialization and shaped by learning and consequences. In fact, dogs have acquired an ability and readiness to respond to human behavior not found in wolves, even if the wolf pup is hand raised and socialized. In turn, dog owners must learn to read canine visual signaling and vocalization to understand when dogs want to engage and when they do not, as well as to train and reward relaxation and to safely and effectively modify fearful and aggressive behaviors.

Canine Development

The first important period of development is the neonatal period, which extends into the third week of life. Puppies are born with closed eyes and limited motor ability. Puppies are altricial; therefore, in the first few weeks, maternal care is critical. Grooming by the mother arouses the puppy to eat, stimulates elimination, and helps to keep the puppies in the nest. Good maternal care results in an increased ability to handle stress and increased maturation of the nervous system. Similarly, mild stress in the form of gentle human handling during the first 2 wk of life can improve cardiovascular performance and resistance to disease. Handled puppies also mature faster, perform better in problem-solving tasks, and are better able to withstand stress as adults. In contrast, moderate to severe prenatal and neonatal stress as well as maternal separation can have a sensitizing effect on the hypothalamic-pituitary-adrenal axis. Feeding the bitch a diet enhanced with

docosahexaenoic acid during the neonatal and prenatal periods has been shown to improve the puppy's brain and retinal development and trainability.

Between the neonatal and socialization period is a transition period, during which the eyes open and puppies begin to develop motor skills. At this time, interactions with littermates are important for development of social skills.

The next period of development (socialization or sensitive period) extends from 3–4 wk to ~12 wk of age. During this period, the puppy is most sociable and will most readily habituate to dogs, people, other animals, and the environment (sights, sounds, odor, touch, taste). Between 3 and 8 wk of age, puppies start exploring their environment and continue to refine social skills with their littermates and other dogs. Weaning is normally completed at 7 wk of age, and at ~8 wk of age puppies start developing a preference for elimination locations.

As the socialization period winds down, puppies make attachments less easily. Therefore, a lack of adequate socialization and enrichment during the sensitive period can contribute to excessive responses to stimuli, including fear and aggression. Spending the first 7–8 wk with the mother and littermates plays an important role in the development of social skills with other dogs. However, if exposure to people, other pets, and new environments does not begin before the end of the socialization period, the dog may become socially maladjusted and unable to cope and communicate. Proper development of social skills can be accomplished in part by adopting puppies into the new home at ~8 wk of age and enrolling in puppy socialization classes before 12 wk of age, so that the puppy can be exposed to a range of dogs, people, and other stimuli (eg, novel surfaces, noises, odors, moving objects, uniforms, and handling) in a controlled, instructional, and positive environment. Similarly, visits to the veterinarian or groomer, car rides, visitors to the home, and the use of sound desensitization recordings provide additional opportunities for exposure. Dog appeasing pheromone and the presence of another dog may also ease adoption into a new home. If there are any signs of fear, every effort should be made to overcome the fear by finding the limits (threshold) the dog will tolerate and using food and treats or toys to try to ensure a positive outcome. Continued exposure to a wide variety of stimuli with positive outcomes should be continued to adulthood.

The third (juvenile) period extends from ~3 mo to 1 yr of age. Domestic dogs reach sexual maturity at 6–9 mo (later in some giant breeds) and social maturity at 12–36 mo of age. Social relationships are established to minimize conflicts within the group. Although heredity and previous socialization play important roles in the behavior of an individual, positive exposure to a wide range of animate and inanimate stimuli during this period should minimize development of fear and anxiety.

Domestic dogs are nonseasonal breeders and have on average two heat cycles/yr (range one to four). If the female does not get pregnant, she will go through hormonal changes as if she were pregnant, known as false pregnancy or pseudocyesis, which can be associated with overt physiologic and behavioral changes, including lactation, nesting, and protective aggression of objects such as toys.

Counseling to Prevent Undesirable Behaviors

Veterinarians and staff should work with breeders, trainers, pet stores, and shelters to ensure that the newly adopted dog gets off to the right start. For puppies, this includes advice on socialization, normal canine behaviors (eg, jumping up, play biting, elimination) and how they can be managed, a household environment that provides appealing but safe outlets for all of the dog's behavioral needs (eg, chewing, social play, object play, rest), guidance on canine communication, and learning principles of reinforcement-based training. The goal should be to reinforce desirable behaviors and to ignore or prevent undesirable behaviors. Clicker training can be particularly useful to immediately mark and reward desirable behavior and gradually shape behaviors that more closely approximate the final outcome (duration, relaxation).

Oral behaviors are a common problem, because puppies have a behavioral need for exploration and play. Therefore, providing constructive social activities that do not include mouthing or biting of people, such as tug games, retrieving, walking and running, chasing, hide and seek, playing with other dogs, and training for rewards, gives the dog something positive on which to focus. A head halter is also an option for better control of the head and muzzle. Another way to manage oral stimulation and exploration is to provide chew toys, food-stuffed toys, and food-dispensing toys.

When the puppy cannot be effectively supervised, the household should be set up to ensure success (and avoid failure). Preventing undesirable behaviors while providing the dog with options acceptable to the owners and the dog gives the dog control to make choices, reduces uncertainty and anxiety, and prevents undesirable behaviors. Of particular value to establish a safe haven is a crate, exercise pen, or room to provide security and safety for the dog when it cannot be supervised or wants to be alone. A daily routine can be established that provides stability and predictability for the dog, beginning with meeting the dog's social and physical needs, followed by sessions of inattention during which the dog is given the opportunity to nap and rest or to engage in exploratory play with its food and chew toys. By confining the dog to a crate, pen, or room during these "inattention" times, the dog learns to spend time on its own; this also may prevent damage to property, housesoiling, and even separation anxiety. Undesirable behavior might alternatively be prevented through environmental management (eg, child gate, shutting doors, tie downs, deterrent devices). Neutering males may also help to prevent testosterone-influenced behaviors such as urine marking, mounting, and roaming.

BEHAVIORAL PROBLEMS

When behavior of dogs is undesirable, there are three levels of consideration: 1) Behaviors within the normal range for the species, age, and breed. In these cases, the owners need guidance on how to effectively manage the behaviors. 2) Behaviors more difficult or challenging, because they might fall within or just beyond the range of what is considered normal but are particularly intense or difficult to manage. Examples include mouthing, urine marking, mounting, barking, chasing, predation, or overactivity. Also in this category might be what could be normal for the breed but unsuitable for the family and home (ie, mismatch). These cases require behavior assessment and counseling to ensure the owners have a realistic understanding of what might be achieved and to implement treatment strategies, including environmental management and behavior modification, to achieve an acceptable level of improvement for both the owners and the pet. 3) Behaviors that are abnormal or pathologic, as a result of emotional disorders or mental health issues. These may have developed as a result of genetic factors, stressful perinatal

environment (prenatal, neonatal), insufficient early socialization, medical conditions affecting brain health and development, or particularly traumatic environmental events. For these pets, the prognosis may be guarded, and owner expectations altered to achieve an acceptable outcome. Treatment generally requires both environmental management and behavioral modification, often in combination with medication (natural products, diet, drugs) to improve underlying pathology and facilitate learning.

The process to diagnose behavior problems and their treatment with behavior modification and drugs has been previously described (*see* p 1539). If the problem is determined to be a normal but undesirable behavior, the owners will need counseling on how to effectively provide for the pet's needs and how to reinforce what is desirable while preventing what is undesirable. For most canine behavior management problems, counseling from veterinary staff or trainers and quality resources are required, as well as hands-on guidance from a trainer. Trainers should be selected based on their credentials and screened to ensure they use reinforcement-based training techniques. Positive punishment-based techniques should not be used in training, because at best they serve only to suppress undesirable behavior and can lead to fear, avoidance, and even aggression. Management issues include inappropriate play (eg, nipping or mouthing of people); unruly behavior (eg, pulling, lunging, jumping up, mounting, overactivity); and some forms of barking, destructive behaviors, and housesoiling.

If the problem is determined to be an emotional disorder or abnormal behavior, resolution will require a combination of behavior modification techniques, modifications to the environment to prevent further problems, and medications to help reestablish a more normal mental state and facilitate new learning (*see* p 1539).

Fears and Phobias

Fear is a normal response to an actual or perceived threatening stimulus or situation. Anxiety is a response to fear and agitation, or apprehension when the animal anticipates a threat or fearful situation. Phobia is an exaggerated fear response (*see* p 1536). The fear response may include panting and salivation, tucked tail, lowered ears, gazing away, low body posture, piloerection, vocalization, or displacement behaviors such as yawning or lip licking.

While avoidance and escape is one strategy, some dogs use aggression to remove the fear-evoking stimulus and are reinforced by success (negative reinforcement).

Some of the more common presentations include the following: 1) fear of other dogs, especially those that are unfamiliar, appear threatening to the dog, or with which the dog has had an unpleasant experience; 2) fear of unfamiliar people, especially those who are novel or look, act, or smell different than those the dog is accustomed to (eg, young children); 3) fear of inanimate stimuli such as loud or unfamiliar noises (eg, construction work, trucks, gunshot), visual stimuli (eg, umbrellas, hats, uniforms), environments (eg, backyard, park, boarding kennel), surfaces (eg, grass, tile or wood floors, steps), or a combination of stimuli (eg, vacuum cleaners, car rides); and 4) fear of specific situations such as veterinary clinics or grooming parlors. Some dogs have a more generalized anxiety, in which the fearful reaction is displayed in a wide range of situations to which a "normal" pet would be unlikely to react. Although there can be a genetic component to fear and anxiety, prenatal and neonatal stressors, including maternal separation, lack of socialization (ie, unfamiliarity), or a previous unpleasant outcome during encounters with the stimulus (or similar stimuli), can also be causative factors.

Phobic responses in dogs are generally associated with loud noises (eg, thunder, fireworks, gunshots) and the stimuli associated with these events, including rain, lightning, and perhaps even static or pressure changes associated with a thunderstorm. Some fears (eg, veterinary clinics, going outdoors, entering certain rooms, or walking on certain types of flooring) may become so intense that they meet the definition of a phobia.

Separation Anxiety: It is estimated that ~14% of dogs have separation anxiety, or an inability of the pet to find comfort when separated from family members. The problem may be primary (eg, hyperattachment, dysfunctional attachment) as the puppy ages and matures; in fact, the chances of the problem developing can be reduced by having puppies regularly spend time during the day on their own (preferably in a safe haven). In other cases, the anxiety about being left alone is secondary to an event such as a change in the household or dog's daily routine, or associated with an underlying state of anxiety along with other behavioral issues such as noise phobias and separation anxiety. Anxiety may lead to

destructive behavior (particularly at exits or toward owner possessions), distress vocalization, housesoiling, salivation, pacing, restlessness, inability to settle, anorexia, and repetitive or compulsive behaviors. The behaviors are exhibited when the dog is left alone and generally arise within the first 15–30 min after departure. A video recording can be an invaluable diagnostic aid to visualize the behavior and determine whether there are other concurrent signs of anxiety (autonomic stimulation, increased motor activity, and increased vigilance and scanning). The diagnosis requires that other common causes of the signs be excluded (eg, incomplete housetraining, exploratory play and scavenging, external stimuli leading to arousal and anxiety, noise aversion, or confinement anxiety). Many pets with separation anxiety begin to exhibit signs as the owner prepares to depart (eg, putting on shoes, getting keys, going to the door). When the owner is home, the dog may crave constant contact or proximity to the owner. When the owner returns, the welcoming responses are commonly exaggerated and the dog is hard to calm down.

Abnormal Repetitive Behaviors

Abnormal repetitive behaviors may actually comprise a number of conditions with different pathogeneses, including compulsive disorders, stereotypies, neurologic disorders, and other forms of behavioral pathology. Therefore, until a diagnosis is made, the term abnormal repetitive behavior may better describe the clinical presentation.

Compulsive disorders may be repetitive, stereotypic, locomotory, grooming, ingestive, or hallucinogenic behaviors that occur out of context to the time and situation in which they take place, and occur in a frequency or duration that is excessive. There may be lack of control over onset or termination. Although it can be debated whether animals can obsess, they do perceive and experience concern; therefore, the term obsessive-compulsive has also been used to describe this disorder. The diagnosis should start with a description and observation of the behavior, including video recordings if necessary. Because there is likely a genetic component for many compulsive disorders, the signalment and age of onset is also important. For example, German Shepherds and Bull Terriers are known to spin or tail chase, while a genetic locus for flank sucking has been identified in Doberman

Pinschers. The problem may first arise as a displacement behavior when the dog is frustrated, conflicted, or highly aroused. Lack of predictability in the daily routine, alterations in the environment, unpredictable consequences, lack of sufficient outlets for normal behaviors, and chronic or recurrent anxiety might be initiating factors. At this point, if the owners can teach appropriate acceptable alternative responses (eg, sitting before greeting or play as an alternative to spinning) and provide constructive alternatives (eg, feeding from toys), the problem might be resolved. However, as the frequency or intensity increases, the behavior may become compulsive. The diagnosis is considered to be a compulsive disorder when the behavior interferes with normal function or when it becomes independent of (or emancipated from) the inciting stimulus. There is likely altered serotonin transmission.

Stereotypies are defined as repetitive behaviors that are unvaried in sequence and have no obvious purpose or function. They may arise when the environment lacks sufficient outlets for the dog to engage in normal behaviors, or when caused by maternal deprivation or as a result of a neurologic disorder. It is possible that stereotypic behaviors, at least in their early stages, may provide a coping mechanism for the pet. Stereotypies might be induced by dopaminergic stimulation.

Although most dogs respond to drugs that inhibit serotonin reuptake including the SSRIs and clomipramine, alterations in other neurotransmitters may play a role, eg, dopamine, endorphins, *N*-methyl-D-aspartic acid (NMDA). Because medical problems might be the cause of the signs, these should first be excluded. In cases in which the physical examination, history, and diagnostic testing do not clearly identify the cause, a therapeutic response trial might be indicated (eg, anticonvulsants to exclude focal seizures as a cause of fly snapping or light chasing; clomipramine or fluoxetine to exclude compulsive disorders). *See also*

TABLE 4.

Aggression

Aggression is the most common problem in referral practices across North America, approximating 70% of the caseload. It is also a major human concern, because at least 5 million people are referred to the hospital each year in the USA alone for treatment of dog bites. Most forms of aggression, except for predation, are

TABLE 4 CLINICAL PRESENTATION AND MEDICAL DIFFERENTIALS FOR COMPULSIVE DISORDERS

Compulsive Disorder Signs	Medical Differentials	Diagnostic Tests / Therapeutic Trials
Ingestive: pica, licking, sucking, swallowing (glugging)	GI, food intolerance	Endoscopy, food trial, steroid trial, GI protectants
Polyphagia, polyuria, polydipsia	Urogenital/renal, hepatic, endocrine	Blood and urine testing, hormonal assays, modified water deprivation test
Dermatologic/self-trauma: nail biting, flank sucking, acral lick dermatitis, psychogenic alopecia, tail mutilation	Atopic dermatitis, bacterial or parasitic hypersensitivity, adverse food reaction, parasite, infection, neuropathy, pain	Dermatologic tests (eg, skin scraping, trichogram, fungal culture, biopsy), therapeutic response trial
Neurologic: spinning, star gazing, pouncing, fly snapping, light or shadow chasing	Focal seizure, neuropathy	Neurologic tests (eg, MRI), therapeutic seizure therapy trial (eg, levetiracetam, potassium bromide, phenobarbital)

distance-increasing behavior (ie, the dog is attempting to actively increase the distance between itself and the stimulus). There are many types of aggressive behaviors with different motivations; however, fear, anxiety, conflict (uncertainty), genetics, and learned responses generally play a role in most cases; however, in some cases the behavior may be abnormal or pathologic. The effects of early development (prenatal, postnatal), socialization, and previous experience all play a role in development of aggression.

Aggression refers to threatening behavior or harmful attacks and can range from subtle changes in body posture, facial expressions, and vocalization to biting. Dogs that are easily aroused are at high risk of aggression, because their decision-making is affected by their physiologic state (ie, flight or fight). For treatment to be effective, the pet's anxiety and arousal must first be managed by avoiding situations or staying below the threshold at which aggression might arise. Some or all of a combination of reward-based training, behavior products that can help to better manage the pet, and medications to help achieve a behavioral state most conducive to new learning is required to successfully modify the behavior to achieve desirable outcomes and countercondition the pet to the stimuli that incite aggression.

Before treating aggression, the practitioner must assess the potential risk of injury. All stimuli that might incite

aggression should be accurately identified to ensure initial safety. Predictability is a critical issue in prognosis, both to prevent further incidents and to develop a stimulus gradient for treatment. The signalment, environment, history, and target of the aggression also provide invaluable information as to whether the problem might be safely and effectively managed. The type of aggression is an additional factor; some can be managed and improved, whereas others require prevention. Finally, the clinician must assess the ability of the owner to effectively and safely prevent the problem. Aggression that is unpredictable, arises during relatively benign interactions, involves targets that cannot realistically avoid exposure to the aggressive dog (eg, young children, other household pets), or is performed by a large dog or in an uninhibited manner worsens the prognosis. Any medical condition that might cause or contribute to aggression must be identified, because they are important factors in diagnosis, prognosis, and treatment. (See www.esvce.org for risk assessment guidelines.)

Fear-related Aggression: Fear is the underlying cause of most forms of canine aggression. It is triggered by a stimulus that is threatening to the dog. When the aggression is a direct response to a challenge or confrontation, it might be referred to as defensive aggression. Fearful

dogs may try to avoid the stimulus but become aggressive if they cannot escape (eg, leashed, confined, cornered, or physically grasped), are motivated to maintain their place (eg, on property, between the owner and stimulus, near food or toy), or if they learn that aggression is successful at removing the threat. Inadequate socialization, learning, genetics (temperament), reinforcement of aggressive behavior (eg, retreat of the stimulus), and associating a negative outcome with the stimulus (eg, punishment) can all lead to the development of fear-related aggression. The diagnosis is based on identifying signs of fear as well as the history beginning with the first event, because dogs can exhibit fear at the initial exposure but with time may display a more offensive form of aggression (without threats) when they learn it can be successful. (For treatment of fear-related and other types of aggression, see p 1565.)

Possessive Aggression (Resource

Guarding): Possessive aggression is most likely to arise when a person or an animal approaches the dog while it is in possession of something it wants to retain. Pets in the process of ingesting or chewing an object might be more likely to display aggression, but the behavior can also be seen in dogs near an object. Aggression is most commonly displayed when in possession of highly motivating food, treats, chew toys, stolen items, or even sleeping places. While genetics and early experience play a role in development, the relative value of the object to the pet and the threat of losing the object to another dog or person determine whether the pet is likely to be possessive. Items that are novel or scarce may be more desirable. Fear and defensive behavior also play a role if the owners threaten, punish, or confront the pet when it takes an object or has it in its mouth. The dog may also learn that it can successfully retain the object with aggression.

The problem might be prevented by tossing the puppy high-value treats whenever the owner approaches or passes by the food bowl, and by offering a high-value treat or toy whenever the puppy voluntarily gives up another toy or chew. Food bowls, toys, and chews should not be removed by confrontation, because this can contribute to an increase in anxiety and aggression when approached. In adult dogs, the problem should be managed by preventing access to these items or confining the dog when it is given items over which it might be

possessive and by training the dog to give and drop on cue (beginning with items of low value for high-value rewards). If safety is an issue (ie, the dog may hurt itself by chewing on the item), it may be possible to trade the object for one of higher value. Providing more toys and multiple small meals (eg, in feeding toys) may reduce the value and novelty of the resource.

Play Aggression: Aggressive play is a normal puppy behavior, which may persist into adulthood as a result of genetics, neotimization, and learning. When puppies play aggressively with other puppies, they may nip and bite but will generally resolve the conflicts among themselves. However, if the problem becomes excessive, owner intervention may be required to redirect the dog's activities into other forms of play (eg, feeding toys) or to interrupt the behavior with commands or a leash and head halter. If play with people escalates to biting, the interaction can be immediately stopped (negative punishment) and resumed when oral play ceases (positive reinforcement). Alternatively, a leash and head halter or verbal distraction ("off") can be used to interrupt play biting. In all interactions, the puppy should be taught to sit before given anything of value (eg, food, toys, affection). In addition, the puppy should be engaged in regular alternative acceptable forms of play, including fetch, tug games, and manipulation and chew toys. Punishment should not be used to stop play, because it can lead to fear of the owner, defensive aggression, or conflict-induced aggression, or serve as inadvertent reinforcement for some puppies.

Redirected Aggression: Aggression is directed toward a third party when the dog is prevented or unable to exhibit aggression to its primary target. This type of aggression is most commonly described when the dog bites the owner as he or she grasps or restrains the dog when trying to prevent or break up a dog fight. Similarly, dogs that might be aggressive toward a veterinarian might bite the person restraining the dog. Redirected aggression arises as a result of the frustration or interruption of other forms of aggression or arousal.

Irritable/Conflict/Impulse Control

Aggression: Aggression directed toward family members is often mislabeled as dominance or status-related aggression. However, aggression toward family members generally arises from fearful or

defensive behaviors, resource guarding, redirected behavior, or situations of conflict (competing emotional states and unpredictable consequences). In some dogs, the problem may be traced back to the owner's attempts to inhibit excessive play aggression (*see above*).

When a dog successfully uses aggression to achieve a goal (retaining a resource) or remove a threat, the pet learns that aggression is successful (negative reinforcement). If the owner continues to threaten, confront, challenge, or punish the pet, some dogs may inhibit their responses, but a large proportion become more aggressively defensive. When dogs are resting or sleeping, chewing on a favored object, or no longer desirous of human affection, they may respond with either deferent displays or threats. However, if the owner continues to approach, tries to remove the resource, or attempts to pet the dog despite its signaling, aggression may escalate and future signaling may be lost. The owner-pet relationship can quickly deteriorate as the dog becomes more wary and defensive while the owner becomes more fearful and/or confrontational.

Genetic factors and early experience likely also play a role; many of these dogs are easily aroused, excessively fearful, or may have emotional disorders or behavioral pathology (*see below*). Other cases are primarily a result of learning. Aggression when grabbing the collar or during bathing, nail trimming, or ear cleaning is a defensive response. Interrupting a pet that is aroused may lead to redirected aggression. Therefore, when a dog is presented for aggression toward family members, it can be difficult to determine the dog's underlying motivation because each incident has added to prior learning, fear conditioning, and underlying conflict. Dominance might refer to the relationship between two individuals of the same species within a social group, as described by actions, interactions, and intraspecific communication/signaling. These relationships are not established by aggression of the dominant individual but rather by the deferent signaling of others. Relationships between species, particularly dogs and people, are established through early socialization, the personality of the individual, and what it learns from its observations and interactions with family members. Physical techniques intended to assert dominance (eg, pinning, rolling over) and verbal discipline (yelling "no") are therefore ill advised and can result in fear, anxiety, and further aggression.

Dogs with impulse control aggression may respond with aggression to relatively benign interactions with family members. In some lines of English Cocker Spaniels and English Springer Spaniels, this aggression is associated with alterations in serotonin in blood samples or CSF.

When aggression is excessive, unpredictable, and disproportionate to the level of threat, safety is a serious concern and the prognosis generally guarded. However, when behavior is abnormal or pathologic, substantial improvement might be achieved with a combination of drugs (eg, SSRIs) and behavior modification.

Aggression Toward Other Dogs:

Dogs in the same group or household usually avoid conflict without aggression. Communication is based on dominant and submissive signals, with the deference of one of the two individuals to avoid escalation of the encounter. Dominance is a relative concept—the dog that displays deferent signaling may vary between resources and situations. Aggression between individuals living in the same household is generally an abnormal behavior caused by fear and anxiety, redirected aggression, impulse dyscontrol, or poor intraspecific communication skills as a result of genetics or lack of early socialization and compounded by experience and learning. Redirected aggression and competition over a valued resource may also lead to aggression between dogs in the home.

Owners may play a role by inadvertently supporting or encouraging a dog during an encounter in which it would normally defer. Age or illness may also play a role, if the way in which one dog signals or responds to the other is altered. Male-to-male aggression may have underlying hormonal factors that can be improved by neutering; however, learning may play a role in maintaining aggression.

If any situations arise in which the dogs are unable to resolve conflicts without aggression or injury, behavioral guidance should be sought. Aggression toward unfamiliar dogs and those that are not members of the family group are likely fearful, possessive, protective, or territorial.

Territorial/Protective Aggression:

Aggression may be displayed when the dog is approached in its territory. Territory can be stationary (eg, yard, home) or mobile (eg, car). What defines the behavior as territorial is that the dog does not display fear to similar stimuli when outside its territory. Fear, anxiety, defensive, and possessive

behaviors may all be components, because the pet is most likely to display the behavior toward unfamiliar stimuli, and the motivation to escape or avoid (flight) is decreased or absent when the pet is on its own property. Learning (negative reinforcement when the stimulus retreats) and fear conditioning (unpleasant outcomes such as yelling, discipline, and confinement) can also play a role.

Predatory Aggression: This is one of the most dangerous types of aggression, because there is usually no warning. The attack is intended to kill prey, and the bite is uninhibited. The sequence of events may include stalking, chasing, biting, and killing. Young children and babies may be at risk because their size and behaviors mimic those of prey. Although extensive socialization to a species might reduce predation toward that species, the behavior may be enhanced when predatory individuals are together in a group. Predation is a normal and dangerous canine behavior; thus, any dog that exhibits the behavior must be prevented from opportunities to repeat it.

Pain-induced and Medical Causes of Aggression: Any disease that causes pain or increases irritability (eg, dental disease, arthritis, trauma, allergies) can lead to aggression. The dog may become aggressive when it is handled or anticipates handling. Organ dysfunction (eg, renal, hepatic, CNS disease, and endocrinopathies (eg, hyperadrenocorticism, functional testicular and ovarian tumors, and thyroid dysfunction) might also contribute to irritability and aggression. (See also TABLE 2.) While hypothyroidism is more likely associated with lethargy, dermatologic signs, and heat seeking in the early stages, it has been suggested that dogs might display an increase in aggression, particularly toward family members. Treatment should likely be reserved for cases in which diagnostic tests are also consistent with hypothyroidism, because excessive supplementation could lead to a hyperthyroid state (with associated medical and behavioral consequences). Treating the medical problem may resolve the aggression, but the behavior, once learned, may persist.

Maternal Aggression: Maternal aggression may be seen in intact females with a litter of puppies or in females with pseudocyesis. It can be directed toward people or other animals. Signs of aggression arise when the bitch's puppies or toys that mimic puppies are protected, and the

aggression should resolve when the hormonal state returns to normal and/or the puppies are weaned. The term maternal aggression has also been used to describe the aggression or cannibalism directed toward the puppies by the bitch. Although the problem may have a genetic component, it is reported to occur more frequently after a first litter. Ovariohysterectomy can prevent further incidents.

Treatment of Fears, Phobias, Anxiety, and Aggression

Before implementing specific therapy to manage, improve, or resolve a behavior problem, some common elements that apply to most cases should be considered. The initial discussion should focus on 1) an understanding of normal behavior as it relates to the problem, 2) learning to read canine body language and facial expressions, 3) ensuring that all of the dog's needs are adequately being met, 4) reviewing the principles of learning and reinforcement-based training (predictable consequences), and 5) managing both the environment and the dog to prevent further incidents. The cause, diagnosis, and motivation behind the behavior should be reviewed. Finally, the owner should be given a prognosis with realistic expectations for both short- and longterm outcomes.

In most cases, treatment focuses on changing the dog's emotional response with the stimulus (counterconditioning) and/or replacing the undesirable response with one that is desirable using reinforcement-based techniques (response substitution). However, dogs that are highly aroused respond with autonomic fight-or-flight responses and tend to make reflexive responses. Therefore, arousal must be reduced before treatment can proceed. This can be achieved by training the dog to settle on cue, by minimizing the intensity of the stimulus during exposure (desensitization), or by using management devices such as head halters that can change the dog's focus and help it to settle, and with drugs or natural products that reduce anxiety and behavioral pathology. Early intervention with medication may be necessary to achieve success and can be in the best interest of the fearful, anxious, or phobic dog.

There are common elements to the treatment of fear, anxiety, phobias, and most types of aggression. The first step in the treatment program is to identify each situation stimulus or interaction in which the problem might arise, so that a preventive

program can first be implemented. Prevention ensures safety (eg, in aggression cases), prevents further damage to the household or injury to the dog, avoids further anxiety-evoking situations for the dog, and ensures no further aggravation of the problem through fear conditioning (ie, unpleasant outcomes) and learning (ie, negative reinforcement if the stimulus retreats).

Prevention can be most effectively achieved by identifying and avoiding any situation in which the dog might be exposed to the stimulus. A leash and head harness, leash and body harness, or verbal commands (when effective) can also prevent access to the stimulus. If avoidance cannot be ensured and aggression is a possibility, then a basket muzzle might be the best alternative.

A common starting point to begin to reduce anxiety, improve communication and training, teach self-control, and allow the dog to control its consequences/outcomes is to establish a program of structured interactions in which the dog is not given anything it values (or wants) until it sits (or lies down). If the owners' response is consistent and predictable by ensuring the dog sits (or lies down) every time a treat (food or toy) is given, the leash is attached, the dog goes in and out of the door or car, or the dog wants affection, the dog will soon learn that the sit or down action is required to get the reward, at which point gradually longer and more relaxed responses can be taught. This is sometimes termed structured interactions, predictable consequences, learn to earn, or "saying please."

Because the ultimate goal is to successfully expose the dog to controlled levels of the stimuli while achieving calm and positive outcomes, it is necessary to determine what behaviors need to be trained to achieve desirable outcomes during exposure training. For example, if problems arise indoors, the dog may first need to learn a focused sit, a relaxed down, and a mat command (or other location such as room or crate). A drop or give command and a come or recall may also need to be trained. When problems arise outdoors, sit and focus or down and settle may also be useful, but loose leash walking, backing up, or turning and walking away may be the best options for stimulus exposure. These behaviors should be learned reliably and consistently in a variety of environments with a minimum of distractions before the owners proceed to a graduated stimulus exposure (see p 1540 and p 1542).

By identifying a range (gradient) of the dog's most favored rewards, the most desirable can be used for training and shaping new behaviors that approximate the final goal; less-motivating rewards can then be used to ensure immediacy and timing of previously learned commands. In addition, a way to minimize and control the intensity of the stimulus will also need to be designed (eg, volume, distance, location). Exposure exercises can then be implemented by setting up situations in which high-value rewards are used to reinforce the desired behavior and condition a positive response during exposure to low-intensity stimuli and gradually proceeding through more intense stimuli. Setbacks can be avoided by determining the level of stimulus intensity at which a calm and positive outcome can be achieved and reinforced, and with the use of management devices such as a head halter (sit, reorient head, turn and walk away) or front control body harness (turn away from the situation) to ensure safety and success. Drugs and natural therapeutics might be used concurrently in dogs with excessively intense or abnormal behaviors to enable the successful implementation of behavior modification.

For noise phobias, controlled exposure can best be achieved through recordings that can be gradually increased after each successful session of desensitization and counterconditioning. Concurrent behavioral management to reduce stimuli (with sound proofing, ear covers, eye covers, crate covers, or white noise) and develop a safe haven to help the dog settle might also help the dog to cope. For separation anxiety, once a regular routine of play, exercise, and training is established, any additional reinforcement should focus on shaping gradually longer inattention sessions when the dog rests or occupies itself with favored chew and food- or treat-filled toys, ideally in a comfortable safe haven (bed, crate, or room) where the owners can house the dog while gradually increasing their time away. Any attention- or affection-soliciting behavior should be ignored, unless the dog is sitting or lying down calmly (sit for all interactions) or resting on its bed or mat. Visual and auditory cues that signal departure should be avoided if possible; alternatively, they can be decoupled from departure by exposing the dog while remaining home, and associating with play and treats (counterconditioning). In addition to preventive and environmental management strategies and behavior modification, drugs or natural therapeutics

can be used to reduce underlying fear, anxiety, arousal, reactivity, or impulse dyscontrol to help facilitate learning; to improve underlying behavioral pathology; and in many cases to improve the behavioral well-being of the dog.

For impulsivity, generalized anxiety disorders, excessive stimulus anxiety, and phobias, selective serotonin reuptake inhibitors (SSRIs) and tricyclic antidepressants (TCAs) are commonly used. Because fluoxetine has been evaluated in and licensed for dogs, it is generally the first choice of the SSRIs, although fluvoxamine, sertraline, paroxetine, and citalopram might be alternatives when fluoxetine is insufficiently effective or adverse effects such as anorexia are an issue. SSRIs are also used to treat compulsive disorders. Among the TCAs, clomipramine is licensed for use in dogs and is an alternative to fluoxetine for the treatment of anxiety disorders and phobias. Because clomipramine is the most selective of the TCAs to inhibit serotonin reuptake, it could be used for compulsive disorders, as an alternative to SSRIs. Other TCAs might be selected for their more potent antihistaminic effects (eg, doxepin, amitriptyline), whereas imipramine has been used as an aid in improving sphincter control with behavioral incontinence. Although the full effect might not be achieved for 3–4 wk, some effect might be noted in the first week. For some compulsive disorders, especially those in which there is a self-traumatic component, gabapentin or carbamazepine might be used concurrently, whereas in those cases in which focal seizures might be causing the behavioral signs, levetiracetam, phenobarbital, or potassium bromide might be used in a therapeutic response trial.

When an anxiety-evoking event can be predicted (eg, thunderstorms, fireworks, owner departure, visit to the veterinarian, car ride, exposure to dogs or strangers on a walk, visitors coming to the home), a benzodiazepine can be given with the antidepressant ~1 hr before the event. Because benzodiazepines have variable effects and relatively short half-lives, their efficacy, dose, and duration should be determined in advance of their therapeutic use. Clonidine, trazodone, or propranolol are other options that might be used adjunctively with SSRIs ~1 hr before an expected fear-evoking event (eg, thunder, fireworks, owner departure). In some refractory anxiety cases, trazodone, clonidine, a benzodiazepine such as clonazepam, or perhaps gabapentin might be used concurrently with an SSRI.

Buspirone, a nonsedating anxiolytic, is another option for ongoing use. Caution should be exercised when using anxiolytics, because some may disinhibit fearful dogs, which could lead to increased confidence and aggression.

Selegiline, which is licensed in North America for treatment of cognitive dysfunction syndrome in dogs, is also licensed for treatment of emotional disorders or chronic anxiety in Europe.

Natural products might be used alone or adjunctively with drugs or other natural products to help calm or reduce anxiety, although evidence of efficacy is more limited. A number of studies support the use of pheromone therapy. Adaptil™ simulates the intermammary-appeasing pheromones produced by the lactating bitch and is available as a spray, diffuser, or collar. Pheromones have been used for anxiety associated with car rides, veterinary visits, separation anxiety, storm and fireworks aversions, and to reduce the stress of adoption and aid socialization. A calming or anxiety-modulating effect has been reported for alpha-casozepine (Zylkene®, a milk protein hydrolysate), *Harmonease*® (containing *Magnolia officinalis* and *Phellodendron amurense*), L-theanine (Anxitane®) and Sin-Susto™ (a *Souroubea* plant blend), and aromatherapy (with lavender). In addition, studies with L-tryptophan in combination with a low-protein diet have demonstrated a possible reduction in some forms of aggression. A commercial diet also has been developed that combines L-tryptophan and alpha-casozepine (Royal Canin Calm®) that might aid in reducing stress and anxiety.

Hyperactivity

Although hyperactivity or attention deficit disorder has been poorly documented in dogs, there have been published case studies of dogs with excessive motor activity and an altered ability to acquire new tasks (learn), sometimes accompanied by stereotypic behaviors. It may be particularly difficult to train such dogs to behaviorally settle. There may also be signs of sympathetic activity even at rest (eg, increased heart and respiratory rate, vasodilation). Affected dogs may respond to treatment with methylphenidate. If no improvement with an initial dose of 0.25–0.5 mg/kg, bid, the dosage can be gradually increased every few days to a maximum of ~2 mg/kg until a measurable therapeutic response is seen (reduced motor activity, heart rate, respiratory rate, repetitive activities),

provided no adverse effects develop. Differential diagnoses include impulse control disorders that might respond to SSRI therapy, and normal behaviors in dogs with behavioral needs that are not being adequately met. In fact, it can be quite challenging to meet these needs in some breeds and individuals, depending on the home and family.

Destructive Behaviors

Many of the destructive behaviors, including chewing, stealing, garbage raiding, and digging, are normal exploratory behaviors that arise when the dog is unsupervised and not otherwise engaged in more desirable activities. A regular daily routine with sufficient reward training, exercise, and social enrichment can help to ensure that these behaviors do not arise when the owners are home, although varying degrees of supervision may be required. When the owners cannot supervise the dog, it should be provided with adequate outlets for exploratory play in the form of chews, food-stuffed toys, or manipulation toys, or in the case of outdoor dogs, perhaps even a designated area for digging. These dogs may also need to be confined away from the areas in which problems might arise or housed in crates, pens, or runs to prevent access to potential targets of destruction. Some dogs engage in destructive behaviors because of anxiety (eg, separation anxiety, confinement, noise phobias). Together with the history, videotaping or camera monitoring is generally the best way to diagnose behavior problems that occur when the owner is absent, as well as assess response to treatment.

Eating Disorders

Behavioral problems related to ingestion include those in which food intake is excessive (polyphagia), inadequate (hyporexia), or too fast (gorging); water intake is excessive (polydipsia); and nonfood items (pica) or feces (coprophagia) are eaten. Medical causes should be excluded first. Some dogs that scavenge do so as a normal component of food acquisition and are reinforced by success. Coprophagia may occasionally have a medical cause, but normal maternal behavior includes consumption of feces and urine of young puppies. In addition, as part of exploratory behavior, many dogs are attracted to and may ingest feces, compost, and prey (dead or live). Similarly, although some dogs with pica and polyphagia have

compulsive disorders, many dogs, especially puppies, begin to chew and ingest nonfood items as part of investigative and exploratory behavior.

Dogs with hyporexia may have an anxiety disorder, and some may develop specific taste preferences and aversions that reduce what they will eat.

Many feeding problems can be improved through a work-for-food program in which dogs are given food as reinforcers for training, with the balance placed inside toys that require chewing or manipulation to release the food. This encourages exploration, makes feeding an enjoyable, time-consuming, and mentally challenging activity, and can limit the quantity consumed and prevent gorging. As with most behavior problems, correcting feeding problems needs to be accompanied by management strategies to prevent access to potential targets at any time the dog cannot be supervised or actively engaged in other chew and play behaviors.

Elimination Behavioral Problems

Housoiling: Dogs may soil in inappropriate locations because of inadequate or insufficient training, as a marking behavior, or as a result of fear or anxiety. However, pain, sensory decline, cerebrocortical disease including cognitive dysfunction, or any medical condition that leads to increased volume, more frequent elimination, pain on elimination, or lack of control, must first be excluded as potential causes or contributing factors.

A detailed behavioral history is necessary to determine whether the dog has ever been housetrained. If not, a housetraining regimen should be reviewed in which the focus is solely on reinforcement of elimination in desirable locations rather than punishment of elimination in inappropriate locations. This requires the owner to accompany the dog to its elimination area (eg, outdoors), reinforce elimination, supervise the dog indoors to prevent or interrupt any attempts at elimination (perhaps with the aid of a leash to ensure continuous supervision), and return the dog to its elimination site at appropriate intervals or if there are signs that the dog is ready to eliminate (eg, sniffing, heading to the door, sneaking away). When the owner is not able to supervise, a combination of scheduling (ensuring that the dog eliminates before departure and having someone return to take the dog to its elimination area before it must eliminate) and confinement training/prevention are required.

Dogs can either be confined away from areas where they might eliminate or kept in an area where they will not eliminate, such as a pen, room, or crate, where the dog eats, plays, or sleeps. Alternatively, the dog can be provided with an indoor elimination area (eg, paper, indoor puppy potty) within its confinement area where it can relieve itself when the owner is gone. Puppies obtained from pet stores or any location where they have been extensively caged may be more difficult to housetrain, because they have never had to inhibit elimination and may have learned to play with or eat feces.

Marking Behavior: Although marking is most often seen in intact males as a form of social and olfactory communication, it is also seen in females (especially when in heat) and in neutered males and females, often as an overmarking of other odors (eg, where other pets have urinated, or on items such as blankets with the residual odor of other dogs, people, or cats). Some dogs will mark when they visit unfamiliar households, especially when another dog's odor is present. There is often a typical posture of a raised or partially raised leg when the surface to be marked is vertical. Fecal marking is uncommon.

Although marking is likely a component of normal communication, it is unacceptable when it occurs indoors. Neutering intact males will reduce the behavior, and good supervision can prevent or inhibit most marking. As with housesoiling, dogs should be confined away from areas that might be marked when owners are not able to supervise. Marking that is related to anxiety may be reduced by identifying and treating the cause, perhaps with the aid of drugs or natural products that reduce anxiety.

Excitement, Submission, and Conflict-related Elimination: Dogs may eliminate when they are overly excited, such as when greeting people. Some dogs will urinate when showing submissive postures (eg, crouching to the ground or turning over to expose the belly) or when highly aroused. Because loss of urine control may be associated with a concurrent desire to both greet and show deferential behavior, many cases may be due to conflicting behavioral motivations. Treatment should focus on avoiding the stimuli (reaching, approach, eye contact) that incite the behavior and avoiding any punishment during greeting, which would add to fear and conflict behaviors. Acceptable alternative behaviors that are incompatible with excitable greeting or

deferent postures can be taught, such as a relaxed sit, or any game or "trick" the pet may have learned such as fetch or giving a paw. Phenylpropanolamine might increase sphincter control, whereas imipramine may improve control and reduce anxiety.

Other Elimination Disorders: Dogs with separation anxiety or other fears and phobias (eg, thunderstorm phobia, firework phobia) may soil during these times.

Aging and Cognitive Dysfunction

The aging process is associated with progressive and irreversible changes in body systems that can affect behavior (see TABLE 2). In older dogs, these might include hepatic or renal failure, endocrine disorders (eg, Cushing disease), pain, sensory decline, or any disease affecting the CNS (eg, tumors) or circulation (eg, anemia, hypertension). To diagnose the cause of behavioral signs in a geriatric dog, a detailed history, physical examination, neurologic evaluation, and diagnostic tests are required to exclude potential medical causes of the presenting signs. Many owners do not report these signs, perhaps because the owners think they are insignificant or assume little can be done. Yet in one study, 30% of dogs 11–12 yr old and nearly 70% of dogs 15–16 yr old had signs consistent with cognitive dysfunction syndrome (CDS). A more recent Internet survey estimated CDS in 14.2% of dogs >10 yr old, with prevalence increasing with age, but >85% of these had not been diagnosed. It is therefore essential that owners be informed of the importance of reporting signs when they arise and for veterinarians to take a proactive approach in asking owners about behavior at each visit. Early detection provides the best opportunity to improve signs and slow the decline of cognitive function.

Aging dogs may exhibit a decline in cognitive function (memory, learning, perception, awareness) that manifests as one or more of a group of clinical signs. These are sometimes referred to by the acronym DISHA and include disorientation, interactions, sleep-wake cycles, housesoiling, and activity changes (which may be decreased or increased and repetitive). In addition, anxiety, agitation, and altered responses to stimuli are frequently reported. The first and most prominent sign of brain aging is a decline in learning or memory, which is generally impractical for pet owners to assess. However, neuropsychologic testing of

older dogs has documented memory decline beginning at 6–8 yr of age and learning deficits by 9 yr of age. CDS in dogs is analogous to the early stages of Alzheimer disease in people, both in clinical signs and brain pathology. As with people, some dogs show minimal to no clinical impairment with age, whereas others develop varying degrees of deficits.

Treatment should first focus on environmental enrichment (both physical and mental stimulation), which has been shown to slow cognitive decline and improve the signs of CDS. Selegiline is a monoamine oxidase B inhibitor that may improve the signs of CDS by enhancing dopamine and other catecholamines in the cortex and hippocampus and by decreasing free radical load. Propentofylline, which is licensed in Europe and Australia for the treatment of dullness, lethargy, and depressed demeanor in old dogs, may increase blood flow and inhibit platelet aggregation and thrombus formation.

A number of natural products, including diets and supplements, have also been shown to have beneficial effects in improving the signs and potentially slowing cognitive decline. Two such diets are Canine b/d[®], which is supplemented with fatty acids, antioxidants, and DL-alpha-lipoic acid and L-carnitine to enhance mitochondrial function, and a specialized Purina One[®] diet that uses botanic oils containing medium-chain triglycerides to provide ketone bodies as an alternative source of energy for aging neurons.

Other natural supplements that have demonstrated efficacy in improving cognitive function include Senilife[®], which contains a combination of phosphatidylserine, *Ginkgo biloba*, resveratrol, and vitamins E and B₆; Activait[®], which contains phosphatidylserine in combination with α-lipoic acid, carnitine, fatty acids, glutathione, and other antioxidants; S-adenosyl methionine (Novifit[®]); and apoeaquorin (Neutricks[®]), a calcium-buffering protein found in jellyfish.

range of differences in both physical and behavioral traits. Most cats are solitary hunters that prey on rodents and other small animals, which is likely why their coexistence with people is so successful. Kittens usually learn to prefer to hunt prey that their mother hunted. Kittens may also develop limited food preferences based on texture and taste if not given a variety of foods when young.

In free-range conditions, multiple generations of related females can live together, which also allows for communal rearing of kittens. Kittens may stay with the social group until 12–18 mo old. Sexual maturity is reached by ~6 mo of age. Queens are induced ovulators and generally cycle seasonally (most often from winter to summer) about every 3 wk if not bred. Weaning occurs at 5–8 wk of age. Although some kittens may suckle much later, this is more likely to be social than nutritional. Early weaning of kittens leads to earlier onset of play and predation.

The socialization period of cats is much shorter than that of dogs and may begin to wane by 7–9 wk of age. During this narrow window, exposure to cats, other animals, people, and a variety of stimuli in the environment is important for prevention of fear. Kittens handled extensively by people at 2–7 wk of age may be friendlier, more outgoing, and have fewer problems with aggression. Hand-reared kittens may lack feline social skills and may be hyperactive in object and social play; however, if a kitten is reared with other cats in the home and provided with play sessions with wand-type toys, these problems may be prevented. Genetics, especially those of the father, also play a strong role in personality. Cats may be behaviorally categorized as active, playful and aggressive, calm and sociable, or timid and shy.

Social play, including biting, chasing, and play fighting, begins around 4 wk of age, peaks at 6–9 wk, and declines at 12–14 wk. Social play may be directed at people, especially if there are no other cats with which to play. Object play begins around 6–8 wk and peaks at ~18 wk of age. Object play simulates the predatory sequence and includes stalking, chasing, pawing, pouncing, and biting and can be directed at objects or social partners.

Cats may develop preferences for particular elimination substrates. Many cats dig before and after elimination (which may be a visual mark or to bury urine and feces). Cats are strongly influenced by scents and may respond by marking with urine (spraying) or feces, scratching as both a

CATS

SOCIAL BEHAVIOR

Cats are social animals that, in feral conditions, live in groups consisting mainly of queens and their litters. The density of the group depends partly on food resources. Because cats have been exposed to less selective breeding than dogs, there is far less breed diversity and a much narrower

visual and scent mark, or rubbing sebaceous glands of the cheeks or body in the environment or on other cats. Urine marking, roaming, and fighting with other cats may be androgen influenced, in which case these problems may be prevented or resolved by neutering.

BEHAVIORAL PROBLEMS

As with dogs, undesirable behavior might be 1) normal behavior but undesirable for the owners (eg, climbing, scratching, and excessive nocturnal activity); 2) behaviors that fall within the range of normal but are at or near the limits, excessive in intensity or frequency, and particularly challenging or disturbing for the home environment (eg, play biting, petting-induced aggression, overexuberant play, play/predation, vocalization, asocial, litter box avoidance); or 3) behaviors that are abnormal, pathologic, or incompatible with living in the home (eg, intercat aggression, fear and avoidance, urine marking). In most cases of normal but undesirable behaviors, the owners require guidance and resource material on meeting the behavioral needs of cats and understanding learning principles to reinforce what is desirable while preventing what is undesirable. When behaviors are at or near the limits of normal, a more in-depth behavior assessment is needed to discuss realistic goals for what might be achieved, how the environment might be managed, and how the behavior might be modified. In some households, it may be impractical to make the changes necessary to achieve an endpoint that meets the owner's needs. In cases when the behavior is abnormal or incompatible with the home environment, a behavior consultation is required to diagnose, determine the prognosis, implement behavior and environmental modifications, and dispense drugs or supplements when indicated to achieve a sufficient level of improvement for the owner and the cat. The most common behaviors seen by veterinary behaviorists are elimination (undesirable toileting and marking) and aggression. Because aggressive encounters in cats may be overt or subtle and passive, their frequency may be seriously underestimated.

For both prevention and treatment, it is important to first ensure that the behavioral needs of the cat are adequately met. This is a particularly important consideration for cats housed exclusively or primarily

indoors. Although individual variability in expression can be extensive, a cat's primary behavioral needs include eating (hunting), drinking, elimination, security, play and exploration, climbing, perching, and scratching. Specifically, hunting and feeding needs might be better addressed by giving food in small portions throughout the day and placing food or treats inside toys that require some manipulation to release the food (batting, chasing, rolling, pawing). To add an element of hunting, the cat can be given opportunities to chase, pounce on, and bite toys the owner dangles or pulls in front of the cat.

Play appears to be motivated by two mechanisms: an initial interest if the toy possesses appropriate characteristics (texture, small size) and rapid habituation. Owners should find a number of toys that interest the cat and play with several different toys until the cat's interest wanes. Cats may also be offered small toys for batting and chasing; boxes or containers to explore; appealing outlets to climb, perch, and scratch; and perhaps an occasional catnip toy (to which 50%–75% of cats respond).

Teaching the basics of reinforcement-based training allows owners to focus on rewarding desirable behaviors (eg, where to eliminate, climb, scratch, or perch). Clicker training (see p 1540) can be particularly useful to immediately time (mark) desirable behaviors and gradually shape outcomes that more closely approximate the final goal. Punishment should be avoided, because it can cause fear and anxiety toward the owners or fear of handling and petting and, at best, will stop the undesirable behavior only when the owner is present. Provided all of the cat's needs are adequately met, the best approach to stop repetition of the undesirable behavior can be to prevent access to areas where problems might arise. Another alternative is to teach the cat to avoid the area by making it unpleasant with taste (eg, cayenne pepper), odor (eg, citrus), substrate (eg, upside-down carpet runner, double-sided sticky tape), or perhaps a motion-activated device (eg, alarm, air spray).

Diagnosis and Treatment

Assuming all possible medical causes have been excluded, a thorough history is necessary to diagnose, determine the prognosis, and develop an appropriate treatment program. In cats, especially those with elimination and marking problems, it is

particularly important to assess the environment either by visiting the home or having the owners diagram the home so that it can be determined how the environment affects the problem and how it might be modified to improve the situation.

Response substitution (training an alternative desirable behavior) can be a useful approach if the cat is reward trained with food or favored toys to respond to one or more simple commands (eg, come, sit). A leash and harness can be used as an aid in training as well as a way to prevent undesirable behaviors and ensure safety. For fearful behavior, access to the stimuli should be prevented, at least in the short term. For example, if cats are fearful or aggressive with other cats or visitors, confinement away from the stimulus is an essential first step to ensure safety as well as to prevent further aggravation of the problem. This generally involves housing the cat in its own room with litter, toys, bedding, and food. When the cat is calm and comfortable, it might then be possible to gradually reintroduce the cat using favored toys, treats, or food for counterconditioning.

Drugs for fearful behaviors that could be used on an ongoing basis include fluoxetine, paroxetine, or clomipramine; buspirone or other tricyclic antidepressants (TCAs) or selective serotonin reuptake inhibitors (SSRIs) might be an alternative. A benzodiazepine such as alprazolam might be used on an as-needed basis for situational anxiety such as car rides. Because of the range of individual variability in behavioral effects and adverse effects, trials with different benzodiazepines should be done in advance to determine which drug and dose achieves the desired effect and for how long. Caution is necessary, particularly with the use of diazepam, for any indication of anorexia or depression, because rare cases of acute and potentially fatal hepatic dysfunction have been reported. In some situations, a benzodiazepine such as clonazepam might be considered on an ongoing basis for a more immediate anxiety reduction and to enhance appetite for counterconditioning. Natural products including the F3 cheek gland pheromone (Feliway® [available as diffuser or spray]), L-theanine (Anxitane®), alpha-casozepine (Zylkene®), and a diet containing both alpha-casozepine and L-tryptophan (Royal Canin Calm Feline™) might also be used alone or adjunctively with drugs or other natural products to help calm, reduce anxiety, or reduce the stress associated with environmental change. The F4 cheek gland pheromone (Felifriend®), associated with social marking (bunting) of

cats, is also available as a topical gel in some countries to reduce fear of people or other cats. With intercat aggression, buspirone or a benzodiazepine might increase the confidence of the victim cat during reintroductions. However, anxiolytic drugs could disinhibit and increase aggression.

Housesoiling

With housesoiling, the first step is always to exclude medical problems, because any condition that affects urine volume, frequency, control, or ability to access the litter box can contribute to soiling. Evaluating the behavioral history is then the primary process to make the diagnosis, determine the prognosis, and develop a treatment plan. Important aspects of the history include whether the elimination is urine or feces, whether urine deposits are vertical (spraying) or horizontal (soiling), duration and frequency of the problem, signalment and temperament of the soiling cat, when and where the cat eliminates, litter box details (number, placement, cleaning, substrate, size), the cat's daily routine, and its home environment.

Urine Marking (Spraying): Spraying is emission of a stream of urine onto vertical surfaces, usually accompanied by elevation and quivering of the tail and in some cases treading of the feet. Marking on horizontal surfaces (eg, owner's clothing, bedding, or countertops) is less common. Spraying is much more commonly seen in male cats, and neutering will reduce or eliminate it in most cats, although ~10% of neutered males continue to mark. Marking may be due to anxiety, such as might arise with introduction of a new cat; a change in schedule, environment, or family (eg, renovations, new furnishings, new baby, marriage or divorce); or unfamiliar visual, auditory, or olfactory stimuli.

Treatment can include a combination of prevention, environmental modification, behavior modification, and medication. Providing more litter boxes and more litter box locations, cleaning the soiled areas with bacterial or enzymatic cleaners, and cleaning the litter box more frequently may reduce or eliminate marking in some cats. Punishment is contraindicated, because it increases fear and anxiety in an already anxious animal. Unless the stimuli inciting marking or the underlying factors contributing to the marking can be effectively resolved, most cats are likely to require drug therapy with either fluoxetine or clomipramine

(buspirone or other SSRIs or TCAs might be an alternative). Feliway[®] feline pheromones in the form of a spray on marked locations or a diffuser in the environment might also effectively reduce marking alone or in combination with drugs.

Inappropriate Elimination: Soiling on horizontal surfaces with urine, feces, or both, can be a problem in males and females. Cats that consistently return to the same location or substrate may have a location or substrate preference. Cats that do not use their litter for urine, feces, or both may be avoiding the litter itself, the litter box, or its location. A common cause of avoidance is any medical problem that might cause painful elimination, increased frequency, lack of control, or difficulty accessing the litter box. If medical problems have been excluded or treated and the problem persists, the focus should then be on the behavioral history. Avoidance might arise because of aspects of the substrate (texture, depth, scent, cleanliness), box (size, shape, hood), or location that reduce appeal; unpleasant experiences at or near the box (eg, insufficient cleaning, noises, pain due to medical problems); or difficulty in gaining access to the box. Although anxiety may not be an inciting factor for inappropriate elimination, cats may avoid the litter or box if fearful (ie, personality) or when there is conflict between cats in the home (whether active or passive). Although substrate, litter box, and location preferences may arise secondary to avoidance, some cats may actually have a preference for a particular odor, texture, or location.

Treatment should focus on providing a litter, box, and site that is most appealing to the cat; reducing or preventing the use of the soiled location; and resolving the underlying factors contributing to the soiling. Appeal might be improved by identifying and resolving potential deterrents (eg, undesirable location, fear-evoking stimuli such as furnace noise, or limited access such as a shared washroom), adding additional boxes or additional sites, finding a more appealing location for the litter, improving access to the litter (eg, larger box, ease of entry, ease of exit), and finding out which litter (eg, sand, clumping, clay, soft towel, scented) and box type (eg, size, shape, height, covered, self-cleaning) is preferred by offering the cat choices to decide. Access to the soiled location might be prevented by blocking access to the area, or the appeal reduced by using odor counteractants in the soiled

area, making the area unpleasant (eg, double-sided sticky tape, upside-down [nubs-up] carpet runner), or changing the function of the area (play, scratching, feeding, sleeping).

Aggression

Aggression Toward People: Aggression toward owners may be fear induced or related to play or predation. Cats that bite during petting may have a low tolerance for physical contact, and some cats bite to keep people from approaching or handling them when they are resting, sleeping, or eating (which may be a learned, fear, or social issue). Aggression may be particularly intense if the cat is approached when it is aroused. When the arousal is due to a stimulus to which the cat cannot gain access (eg, another cat outside, loud noise), the cat may redirect its aggression to any person who approaches.

Some cats display abnormal and out-of-context social responses, including aggression, when approached or handled. This may have a genetic component that is compounded by insufficient socialization, lack of adequate maternal care, inadequate early handling, and fear-evoking or traumatic early experiences. However, at the time of presentation, most aggression also has a learned component, because any unpleasant response on the part of the owner (eg, fear, punishment) will cause increased fear, whereas retreat of the owner negatively reinforces the behavior. Aggression toward strangers most often has a fear component.

Aggression Toward Other Cats: Cats may display aggression toward other cats due to play, predatory behavior, redirected behavior, fear, and perhaps as a status-related behavior in which cats use aggression to retain control of sleeping areas, common areas, or possessions. Ultimately, the relationship that develops between any pair of cats will be affected by learning, because fearful responses by either cat can increase aggression, as will retreat of one of the cats (negative reinforcement). Aggression toward unfamiliar cats is most often a fear response but may have a territorial component.

Treatment: The first step is to ensure that further injuries are prevented. Avoidance (physical, visual, and preferably olfactory separation of cats that are fighting) is paramount, and early intervention is best. Although some cats will need to be

separated at all times until they are calm enough to be reintroduced, if there are particular times or situations when conflicts arise, it might be necessary to separate the cats only at these times. Only after the cats are calm (which can take days to months) can desensitization and counterconditioning with favored rewards begin (ie, play with toys, treats). Desensitization and counterconditioning might first begin with odors by grooming each cat with a brush or towel used on the other, and by feeding each cat separately in a common area on opposite sides of a partition (glass, screen, or solid door) and then in a common area at sufficient distance that the cats can be calm and take food or play with toys. Training one or both cats to wear a leash and harness can help to ensure safety and distance during reintroductions, while a bell on the aggressor can help the victim be aware of its whereabouts. Providing more three-dimensional space, including climbs and perches, and ensuring sufficient resources at sufficient distance to facilitate avoidance can further decrease conflict. Reward training limited to a few selected verbal cues (eg, come, sit, go to your room) can further aid in managing the cats during introductions or in diffusing potentially aggressive situations. Punishment should be avoided, because it increases fear and anxiety in cats. Drugs might also be indicated (*see p 1565*).

Feline Compulsive Disorders

Abnormal repetitive behaviors in cats are derived from normal behaviors such as stalking, chasing, grooming, etc. These may be exacerbated by stress or anxiety such as alterations in relationships with people or other cats, or may be inadvertently aggravated by the owners either reinforcing or punishing the behavior (increasing conflict and anxiety). If these behaviors occur out of context or in a frequency or duration in excess of that needed to accomplish the task, a diagnosis of compulsive disorder should be considered. Medical problems must be excluded, because they can be responsible for many of the same signs. For example, self-mutilation, excessive grooming, and/or self-directed aggression can be due to any condition that might cause neuropathic pain or pruritus such as adverse food reactions, atopic dermatitis, and parasitic hypersensitivity.

Cats that suck, lick, chew, or even ingest non-nutritive substances—including natural materials such as wool or cotton, synthetic fabrics, plastic, rubber, paper, cardboard,

and string—may have a compulsive disorder if the problem becomes sufficiently frequent or intense; however, disease processes, in particular those that might affect the GI tract, should first be excluded. Oriental breeds develop pica, particularly sucking of woolen objects, more frequently than other cats. Hallucinatory and locomotory compulsive disorders are less common than in dogs; however, painful conditions and any disease process affecting the neurologic system first need to be excluded.

Cats often improve with modifications to the environment that provide more control and predictability and increased enrichment, combined with medications that augment the amount of brain serotonin such as fluoxetine and clomipramine.

Hyperesthesia

Hyperesthesia may not be a specific disorder but rather a sign of underlying medical or behavioral problems. Most commonly, the skin along the lumbosacral area may twitch or ripple. There may be excessive self-grooming, hissing or biting at the back or flank, and intensive tail wagging. Some cats cry, dash away, and even defecate. These episodes arise when the cat is highly aroused and may be incited by physical contact or external stimuli. A compulsive disorder is a consideration when the intensity, frequency, and duration of these problems is sufficiently severe. However, medical causes such as neuropathic pain, dermatologic conditions, myopathies, and focal seizures can also present with similar signs. Therefore, a therapeutic response trial for neuropathic pain, seizures, pruritus, or compulsive disorders might be part of the diagnostic process.

Fear

Fear may arise in cats as a result of genetic factors, lack of sufficient early socialization and exposure, or fear-evoking experiences. The fear may be of unfamiliar people, unfamiliar cats, dogs, noises, or places and situations such as car rides, veterinary visits, and unfamiliar environments. Some cats may also be fearful of familiar people and cats. This may be evidenced as threatening displays and overt aggression (*see above*) or avoidance, withdrawal and hiding, and possibly spraying.

Treatment should begin with identification and avoidance of any situation, stimulus, approach, or handling that might lead to fear. When the cat is sufficiently

calm, gradual improvement might be achieved with desensitization and counterconditioning. Drugs might also be indicated (*see* p 1573).

Aging and Cognitive Dysfunction

Aging and younger cats have similar behavior problems; however, the likelihood of a pathophysiologic underlying condition is higher in older cats. Many diseases, including those affecting the CNS, metabolic and endocrine systems (eg, renal disorders, hyperthyroidism), sensory decline, and pain (eg, arthritis), may present with behavioral signs. Once medical problems have been excluded or treated, behavioral therapy may be required. Behavior problems in senior pets may be more difficult to resolve because of a decline in cognitive function, medical problems that cannot be entirely resolved, and drug contraindications or adverse effects.

Cognitive dysfunction syndrome (CDS) is less commonly reported in cats than in dogs. Yet in one study, ~35% of cats >11 yr old displayed at least one sign of CDS, and 50% of cats >15 yr old showed two or more signs. Brain changes are similar to those seen in CDS in dogs (*see* p 1569). Environmental enrichment and mental stimulation is paramount to prevent and treat CDS. Medications, diets, and supplements might also improve the signs of CDS or slow its progression. Although no drugs or diets are licensed for feline CDS, selegiline and propentofylline have been used off-label. Both S-adenosyl methione (Novifit®) and a commercial diet containing antioxidants, arginine, B vitamins, and fish oil have demonstrated improvement in learning and memory in geriatric cats. Cognitive supplements containing antioxidants, vitamins, and phosphatidylserine (Senilife®, Activait®) have also been developed for cats.

THE HUMAN-ANIMAL BOND

Companion animals are commonly considered to be family members, and the human-animal bond has become a household term. More than half of all households in the USA have at least one dog or cat, and most pet owners have more than one pet. Cats outnumber dogs as companion animals, and many veterinary practices serve only cats. Yet, a 2008 study of the care pets receive reported that dogs were seen by a veterinarian more than twice as often as cats, even in households with both species.

Households with children are the most likely to have pets. Most couples also have pets, including retired couples, who have recently shown a growth rate in pet ownership. Currently, fewer than half of single persons have a pet. In dealing with owners, using approaches that incorporate the entire family is an important feature of a successful veterinary practice.

With the growing awareness of the human-animal bond, the roles of pets as service and therapy animals are expanding into new areas and fill many of the same support functions that people do. Service dogs assist people with various disabilities, including mobility, visual, or hearing

impairments. The dogs may also detect and alert people to impending seizures or abnormal blood glucose levels.

The human-animal bond has also increased focus on ensuring that animals receive adequate consideration and care. Albert Schweitzer's concept of "reverence for life" has become a standard for decision-making concerning animals. Acknowledgment of the human-animal bond has become a cornerstone of veterinary practice, and evidence suggests that practitioners who pay close attention to the various aspects of the human-animal bond will thrive both financially and in terms of finding their work enjoyable and rewarding.

VETERINARY FAMILY PRACTICE

The evolution of the role of pets in human affairs has opened new opportunities for veterinarians, especially those in family practice. Owners become deeply attached to and care about the health and well-being of their companion animals. Their expectations for veterinary care are becoming similar to the care ideally provided in human medicine, particularly

as high-tech medicine expands within veterinary specialties. In addition, the current increased importance of animals changes the nature of veterinary practice to include the entire family, and a sophisticated level of family support is expected by many clients. The style and emphasis of companion animal practices have shifted, as reflected in the term "veterinary family practice."

Practices that include the entire family build lifelong relationships with families and their animals. Clients look forward to consistently seeing the same veterinarian. A new animal brought into the family is the occasion to discuss the animal's life cycle with the family and provide an overview that can optimize the likelihood of a positive human-animal relationship with few behavioral problems. Veterinarians no longer just treat the animal; emotional needs of the family are addressed along with the medical needs of the pet.

Many families with companion animals have young children, particularly families that have both a dog and a cat. Animals are acknowledged to play a central and formative role in children's lives. In some studies, pet-owning preadolescents scored higher on measures of self-esteem and autonomy. Practitioners may consider incorporating children into their communications with the family and making it easy for families with children to be comfortable during veterinary visits (eg, providing a play area in the waiting room or planning for children to be present in or visibly near the examination room). Hospitals providing extended care for animals with complex diagnostic procedures and treatment plans that require hospitalization sometimes find entire families coming in to offer support to the animal, perhaps spending hours with the pet; these hospitals may want to plan accommodation for such families.

Providing areas for relaxation, softer light in public areas, and comfortable seating in exam rooms without barriers from the medical staff are some features that improve client satisfaction. Impeccable cleanliness also matters. Veterinary practices that exhibit these values demonstrate the understanding that medical interventions carry emotional consequences and that medical competence and providing emotional support go hand-in-hand.

Studies have shown that communication has a key role in the owner-pet and client-veterinarian bond, because it affects the care pets receive. Effective communi-

cation significantly affects the loyalty of the pet owner to the veterinarian. Pet owners are more concerned with the health and well-being outcomes for the animal, whereas veterinarians often emphasize time and services in their communications. Clients value the genuine love and interest veterinarians show for the animals. The veterinarian's empathetic concern expressed through effective communication builds relationships with clients and enhances client satisfaction. Focus groups have revealed that clients expect veterinarians to educate them, explaining important information clearly and in various formats. Clients want to be provided options and offered a respectful partnership with the veterinarian in the health care of their pet. They expect interactive, two-way communication that includes listening and asking relevant questions. Clear recommendations and effective communication of their rationale also lead to better adherence to medical and treatment plans.

A strong owner-animal bond is associated with greater attention to veterinary care. Owners feel strongly about the quality of life of their pets, as revealed in studies involving surgery or medical problems of pets. Owners want effective pain management for the animal before, during, and after surgery, including spaying or neutering, even though they may not wish to administer such medication at home. People feel that a good quality of life for their pets includes mobility, play or mental stimulation, health, and companionship. Owners of dogs with heart disease expressed extreme concern regarding their inability to subjectively assess whether their pet is suffering. Teaching owners to assess and improve the animal's quality of life is an important aspect of veterinary care and client education. Veterinarians and owners can use a quality of life scale (eg, the HHHHMM Scale to monitor the pet's hurt, hunger, hydration, hygiene, happiness, mobility, and more good days than bad) as an aid in assessment. A strong majority of owners indicate they would trade their pet's longevity for quality of life. Among variables of quality of life, the pet's ability to interact with the owners was the most important.

Good communication skills also build strong client-veterinarian bonds, and successful veterinarians pay close attention to their nontechnical competencies, including interpersonal relationship-building skills. Such skills enable veterinarians and staff members to facilitate clients' understanding of medical situations and preventive medicine

throughout the animal's life, from encouraging clients to attend puppy socialization classes to preparing clients to provide palliative care or deal with end-of-life issues. Follow-up communication can also improve client adherence, which is generally lower than believed by veterinarians. Curricula for veterinary students increasingly include opportunities to develop communication skills, allowing students to practice engaging clients, asking open-ended questions, offering reflective listening and empathy, educating clients, meeting clients' and patients' needs, and emphasizing support and partnership.

Despite optimal communication skills, research has unfortunately shown that veterinarians inevitably encounter owners who are inattentive, neglectful, over-involved, or completely cost-driven, as well as pets that are uncontrolled, dangerous, or dirty, adding to medical and emotional problems. Almost all veterinarians feel they were not prepared by their education and training to deal with such nonmedical issues. Making plans in advance and developing specific protocols for interventions can prepare the veterinary staff with strategies for these situations.

HUMAN HEALTH BENEFITS OF PET OWNERSHIP

Animal companionship both relaxes and entertains people. Pets can provide both social support and status. In coming to know their clients, veterinarians can assess the importance of the pet to a family and the extent to which the family members benefit from the potential psychosocial effects of living with an animal. The pet's contribution may be magnified for vulnerable people, such as older adults who are facing increasing disabilities and losses of close companions and family. During stressful periods in people's lives, many studies have reported that pets offer meaningful comfort that is protective against depression and loneliness. Older women score more favorably on measures of mental health, and college-aged women report less loneliness if living with a companion animal rather than alone.

Similar comforting effects of animal companions, whether cats or dogs, in warding off depression were reported for patients with Alzheimer disease. The same is true for men with AIDS who had a companion animal and were cared for at home and whose social lives were shrinking. Older people experiencing typical life stresses are less affected

(as measured by number of medical visits) when they have a companion dog, suggesting that a dog can be a stress buffer that softens effects of adverse events on the person. Of course, pets require caregiving, and the reciprocal caregiving exchanged with the animal can also allow the person to nurture and feel needed, while also feeling nurtured. The animal's constancy bolsters courage during setbacks, because the animal's affection is unaffected by factors such as the person's physical capabilities or mood.

Companion animals facilitate social interactions with other people and an overall positive social involvement. The socializing effects of dogs have been documented in public settings and also among people with a variety of disabilities. A companion animal provides a person who has few friends with an ally in making new human acquaintances, while also creating a richer family environment with enhanced companionship. Even one person with an animal lives in a family unit and is greeted or recognized on arrival home.

The motivating role of animals is a further antidote to depression. Many people are inspired to walk their dogs, volunteer to take animals into nursing homes for visits, or just actively nurture an animal, whereas without the animal they may be less involved and engaged in living or even depressed. Walking a dog and being outdoors where other social contact arises are two healthful effects of living with a canine companion. Research projects and community programs in many parts of the USA and elsewhere are seeking to raise the popularity of dog walking as an approach toward improving human health and lessening human disease, including diabetes and cardiovascular problems.

The daily comfort, socialization, and relaxing motivation offered by an animal also are associated with cardiovascular benefits. Blood pressure decreases transiently when a person relaxes with, talks to, or just watches an animal. When human patients with increased blood pressure were given medication and randomly assigned pets, those patients with pets performed better on stressful tasks, indicating a lower response to stress in this group; however, blood pressure scores did not differ in those with pets and those without. Several studies show longterm health correlates with animal companionship, although the animals were not randomly assigned to the people but rather were chosen by them or their families.

Cardiovascular measures were better among pet owners than nonowners in a large Australian study. Two studies reported that pet ownership was related to decreased mortality. Survival for 1 yr after heart attack was found to be more likely among people with companion dogs, along the lines of human social support.

ANIMAL-ASSISTED INTERVENTIONS: THERAPY, ACTIVITIES, AND EDUCATION

The field called animal-assisted therapy originated when the public began to take animals into nursing homes and other facilities to share them with residents. Unless medically supervised, these programs are termed "animal-assisted activities," whereas those directed as part of medical treatment are termed "animal-assisted therapy." An emerging area is animal-assisted education, in which animals are provided to help improve classroom behavior or learning of children. Procedures to screen animals and provide training for the people involved are offered and have been standardized by Pet Partners (formerly the Delta Society). However, programs that train and certify "therapy animals" (mainly dogs) are not legislatively required as part of a certification process; likewise, there is no conventional educational process for individuals seeking to work in this area. Therapy dogs have no special rights of public access and are not granted special privileges in housing or transportation.

An accreditation process has been developed for instructional programs serving health professionals through the International Association for Animal-Assisted Therapy. The University of Denver offers social work students an emphasis in animal-assisted therapy. Some individuals within human health professions, such as clinical psychology, social work, occupational therapy, physical therapy, and/or nursing, have incorporated animal-assisted activities and therapy with therapy dogs into their professional practice.

A much larger number of people continue to volunteer to bring their animals into facilities, often with some screening process and training organized by local groups. Such groups often benefit from veterinary assistance and leadership in developing appropriate screening methods for selection and preparation of both animals and people participating in these programs.

SERVICE OR ASSISTANCE DOGS AND OTHER WORKING DOGS

If periodic exposure to an animal via animal-assisted activities, therapy, or education is healthful for someone with special needs, more frequent or continual exposure may offer even greater benefits. Service or assistance dogs are trained to perform specific tasks in partnership with people who have disabilities. In addition to guide dogs for people with visual disabilities, hearing dogs for people with hearing disabilities, and service dogs for people using wheelchairs, dogs can assist people with many other disabilities, such as detecting an impending seizure, detecting high or low blood glucose levels in a person with diabetes, or helping to stabilize a child with autism. A growing role of service dogs is as psychiatric service dogs, assisting persons with mental illness such as post-traumatic stress disorders, schizophrenia, bipolar disorder, agoraphobia (fear of open spaces), or anxiety. Other working dogs assist in law enforcement, agricultural or bomb sniffing, search and rescue, or war tasks. Service and assistance dogs have legally protected special access to use public transportation through the Department of Transportation and for housing through the Department of Housing and Urban Development. Some working dogs are kenneled in a facility when not working, although many police dogs live with the families of their handlers. Dogs range from being purpose-bred with extensive training, to being shelter-sourced with minimal formalized training. Significant investments of money and time are required for the specialized training and development of working partnerships with these dogs. As they forge working partnerships with their dogs, the handlers inevitably become emotionally bonded. Formally trained assistance or service dogs can have several trainers or handlers in their early lives, but after being placed, typically spend the rest of their lives with a single handler, providing assistance to the handler while also offering relief and comfort to other family members.

Also based on "equal accommodation" for people with disabilities, "emotional support animals" (ESAs) are another category of animals assured legally protected special access to transportation and housing if they provide a nexus of support for someone with a disability; however, they lack the broader aspects of

public access provided to service dogs. Handlers of ESAs (and psychiatric service dogs) may be asked by landlords or transportation personnel to provide documentation from their medical professionals that they have a disability alleviated by the ESA. ESAs require no special training; they naturally offer special support. ESAs are not limited to dogs but can be of various species so long as they are helping the person who has the disability.

With limited oversight of service dogs and ESAs in the USA, permissive enforcement of requirements, and an expanding array of service dogs and ESAs, dogs of many different breeds and body sizes are providing meaningful support to people with a variety of disabilities. Smaller dogs are easier to manage for people who are frail or live in small apartments, and they may be sufficient for a person's needs, eg, in their capacity to retrieve dropped items. Informed veterinarians can offer wise counsel in these matters to people with disabilities regarding the needed training, medical care, and breed selection. This service is valuable, because the growing demand for service dogs has resulted in some cases of poorly trained dogs at high prices being presented for sale as purported service dogs.

Working dogs are extremely precious and valuable to their handlers. When a medical crisis arises with such a dog, the veterinarian is often the closest professional at hand and may need to provide support to the handler as well as the animal. Treatments that adversely affect performance, especially for an extended period, disrupt functioning of both the dog and the person. If the individual has a disability, special accommodation may be required for communication and veterinary instructions. Treatments not involving an emergency should be planned well in advance, with consideration of the handler's needs and schedule. Attentive listening and respect, although essential for all clients, assumes particular importance in these relationships.

Although no legal or regulatory process certifies assistance dogs, Assistance Dogs International is one organization engaged in developing international standards. Curricula for professionals interested in continuing education in this area are being offered by the Bergin University of Canine Studies in Santa Rosa, California (formerly the Assistance Dog Institute), leading to a Master of Science in Canine Life Sciences.

ANIMAL WELFARE

Reducing or preventing the incidence of animal pain or distress and promoting animal well-being (and even pleasure) are overall goals of animal welfare. These goals pertain to animals on farms or in laboratories as well as companion animals. Aversive handling, even if infrequent, can have stressful consequences. Veterinarians are often the first contacts when someone seeks help for animals being badly treated or receiving inadequate care.

Intentional, deliberate abuse of animals is an extreme marker of a likely pattern of abuse elsewhere within a family. Veterinarians who report suspected animal abuse sometimes can avert similar abuse of other vulnerable family members, especially children or older adults. Two studies reported that >90% of veterinarians would report cases of suspected animal abuse to authorities. Most agreed that animal abuse in families would tend to be linked with abuse or mistreatment of children or older adults.

Although occasionally seen by veterinarians, outright abuse appears less common than the neglect, poor husbandry, or lack of essential medical care of animals, some of which may be inadvertent. A serious problem occurs with animal hoarders who may be mentally ill. The person, perhaps without awareness, acquires more animals than they can possibly care for properly. Some communities routinely combine efforts of animal control and mental health agencies when dealing with such cases.

A major, widespread societal problem of animal welfare is the abandoning and killing of companion animals. Relinquishment of animals that would be adoptable has decreased, yet the problem remains widespread. Many studies have shown that behavioral problems of animals and owners' lack of knowledge of how to adequately care for an animal increase the likelihood of relinquishment. Veterinary teams can provide leadership and education about more realistic expectations of companion animals and can encourage earlier intervention if problems arise.

Despite the growing population of dogs and cats, the number of veterinary visits has been decreasing, raising concerns about whether pets are getting adequate veterinary care. Cats receive less veterinary care than dogs; a 2011 study found that 40% of cats had not been to a veterinarian within the past year, compared with 15% of dogs. Most of these cat owners said their pet

"hated" going to the veterinarian. A cat's resistance to veterinary visits can be addressed by facilitating transport in carriers; making the visit, examination, and treatment more comfortable for the cat and owner; or considering mobile veterinary services.

Some emotionally charged issues and social conflicts pertaining to animals reflect contrasting perspectives on animal welfare. How best to deal with feral cats and their kittens can be a contentious question when weighed against the impact on songbirds and other wildlife. Another emerging concern is the possible adverse medical effect of early neutering for some breeds of dogs, such as a potentially increased incidence of hip dysplasia or certain cancers. Although early neutering curtails unwanted reproduction, other options also could be offered to owners to manage reproduction. As contentious topics regarding animal welfare arise in communities, veterinary professionals are those more prepared to offer reasoned and informed leadership to address problems.

EUTHANASIA, PET LOSS, AND GRIEF FOR OWNERS AND VETERINARIANS

When a beloved animal companion dies or is ill, people are likely to feel stress, sorrow, and grief. This may include the animal's family and neighbors in the community, as well as the veterinary team that provided care. The significance of pets dying and the consequent emotional impact on owners is clearly profiled within the veterinary profession, and educational materials and support groups, hotlines, and counseling are available. The relatively short life span of dogs and cats means that owners face losing several animals during a lifetime.

An extra burden comes in assuming responsibility for the moment of death by euthanasia. The desire or perceived duty to relieve pain and suffering may need to be weighed against the feeling of some owners about the wrongness of killing or a religious argument for reverence for life. The difficulty of this decision overlays the loss with feelings of guilt and the thought that there must have been some other step that could have been taken. Even with family support, these feelings may not be assuaged. Among married couples in one study, approximately half of the wives and more than a quarter of husbands reported they were quite or extremely disturbed by the death of the family pet.

As an alternative to euthanasia, it is important to offer instruction in palliative care for owners prepared to provide it. Procedures developed in hospice care can assure high-quality, end-of-life care with pain relief for animals, and help the family as well. The technical aspects of treatment no longer override the compassionate care, as a specific approach is often offered to deal with the family's and pet's distress.

Owners are also concerned about the care of their pet's remains. Veterinarians offer the available choices, with information about the final disposition of the pet's remains. After a cremation, some owners are concerned to know that the ashes they receive are, in fact, those of their own pet. Veterinarians' communication with clients concerning questions around euthanasia and the care of pet remains is especially important, as is providing support during the mourning process.

Compassionate veterinarians include themselves in the circle of remembrance of their clients' animals and respect the families' regard for the animal throughout the relationship. Many grieving owners need a year of recovery to pass through the holidays and family traditions before somewhat accepting a loss, and veterinarians may consider sending a remembrance card to the family after a year.

SELF-CARE FOR VETERINARIANS

Notwithstanding the anguish that pet owners experience, the process of animals dying, especially the act of performing euthanasia, poses an emotionally wearing duty for veterinarians as well. A recent USA survey found that a veterinarian typically euthanizes more than seven animals per month, sharply contrasting with a study of veterinarians in Japan, where the median number of euthanasias in the previous year was one, and 20% of Japanese veterinarians had not euthanized any pets that year. In one study, euthanizing animals resulted in perpetration-induced traumatic stress for 11% of the study sample of veterinarians, veterinary nurses/technicians, and research and animal shelter staff. Lower levels of stress were reported among those who were more satisfied with their social support and had worked longer with animals. Most veterinarians in another study reported having been clinically depressed. In one study, almost all veterinarians felt they were untrained in explaining euthanasia to clients. Almost half regretted a specific occasion of

euthanasia, and most private practitioners reported feeling guilty after performing euthanasia. After euthanizing their own pets, a majority of veterinarians felt depressed, and 30% felt guilty. These figures were higher among female veterinarians, suggesting that its impact may have risen with the gender shift of the profession.

A major concern with regard to the mental welfare of veterinarians is the suicide rate, which is higher than that of the general population. The suicide rate of veterinarians in the UK is four times that of the general population; although precise figures are not available, similar problems are arising in the USA. Risk factors mentioned in the UK include the initial entry

into a helping profession, routine involvement with euthanasia and knowing the means to perform it, and the contagion of emotional stress. This work became the lynchpin for VetLife: Looking After the Veterinary Profession (www.vetlife.org.uk/), a Web site to support the well-being of veterinarians and to address personal and professional issues.

Increasingly, veterinary students and practitioners realize the value of ongoing monitoring of their own self-care and make use of instruments such as a Self-Care Assessment Worksheet. This brief inventory offers support to keep one's life in balance with a detailed inventory of physical, psychological, emotional, spiritual, and professional self-care.

COLLECTION AND SUBMISSION OF LABORATORY SAMPLES

Each veterinary diagnostic laboratory offers a unique set of diagnostic tests that is subject to frequent changes as better tests become available. The increasing availability of tests based on newer molecular biology techniques is an excellent example of this trend. The protocols for sample collection and submission are therefore also subject to change. The practitioner and diagnostic laboratory staff *must* maintain good communication to complete their diagnostic efforts efficiently and provide optimal service to the client. Practitioners must be specific and clear in their test requests. The laboratory staff can provide guidance when there are questions regarding sample collection and handling, as well as offering assistance in interpretation of test results. Most diagnostic laboratories publish user guidelines with preferred protocols for sample collection and submission, but the following broad recommendations are fairly standard.

Regardless of the type of submission, a detailed case history should be included with the samples to assist laboratory personnel in determining a diagnosis. The information should include owner, species, breed, sex, age, animal identification, clinical signs, gross appearance (including size and location) of the lesion(s), previous treatment (if any), time of recurrence from any previous treatment, and morbidity/mortality in the group. If a zoonotic disease is suspected, this should also be clearly indicated on the submission form to alert laboratory personnel. The submission form should be placed in a waterproof bag to protect it from any fluids that might be present in the packaged materials. Waterproof markers should be used when labeling specimen bags and containers. When packaging samples, the use of breakable containers should be avoided, but properly padded glass tubes are commonly shipped. The basic principles of good shipping practices include the use of sturdy containers, clearly labeled to contain biologic diagnostic specimens; ideally, this should be a styrofoam container within a cardboard box. Any coolant packs should be sealed within plastic bags and accompanied by adsorbent material within the container. If dry ice is used, this should be

noted on the cardboard box label, and the styrofoam lid should *not* be sealed with tape. A “triple barrier” approach can be applied to most diagnostic specimens. One barrier is the outer cardboard box; another is the inner styrofoam container or perhaps sealable plastic bags (with adsorbent material). Note that if air shipment of samples is anticipated, then International Air Transport Association (IATA) requirements include specialized bags capable of withstanding 95 kilopascals of pressure. The third barrier is around the sample itself. Liquid samples should not be shipped in plastic bags; a sealable tube or jar should be used. The top of these fluid-filled containers should be sealed with tape. The tube/jar is then placed in a sealable plastic bag with some adsorbent material in case of leakage. Fresh tissue samples are similarly placed within a second bag (third barrier) containing some adsorbent material. Use of appropriate padding material within the box will protect sample integrity while preventing coolant packs from crushing samples. Regulations regarding shipping of biologic samples vary according to country but in the USA are mainly in the purview of the Department of Transportation, Hazardous Materials Regulations. Also, IATA restricts the volume of formalin that can be shipped in any single shipping container to <1 L in total and <30 mL per jar.

Histology: Tissues for microscopic examination collected either via biopsy or during necropsy can be critical to obtaining a diagnosis. Use of this relatively rapid and inexpensive diagnostic technique can often result in substantial savings in time, money, and animal life. The increasing number of immunohistochemical (IHC) tests that can be applied to formalin-fixed tissue has further reinforced the utility of this diagnostic technique.

Autolyzed tissues are generally useless for histopathologic examination; prompt necropsy examination and organ sampling are critical. Tissue should *not* be frozen before fixation. Other than CNS tissues (*see below*), samples collected for histology should never be >1 cm thick (preferably 5–7 mm) and must be placed immediately into ≥10 times their volume of

phosphate-buffered 10% formalin to ensure adequate fixation. Tissues collected for histologic examination should be representative of any lesions present and, in the case of cutaneous punch biopsies and biopsies obtained via endoscopic collection, should be centered directly on the grossly visible lesions. Wedge biopsies or tissue samples collected at necropsy should include some of the apparently normal surrounding tissue; the interface between normal and abnormal may provide key information. Excisional biopsies of small tumors (<1.5 cm) may be cut in half. Larger tumors may be sliced like bread so that formalin can penetrate to the face of each slice. Alternatively, several representative samples (7 mm wide, including the interface of normal and abnormal) may be collected. The tissues should remain in fixative for ≥ 24 hr; after this initial fixation, the samples may be placed in a smaller volume of fresh formalin for shipment if necessary. Prolonged fixation can adversely affect IHC testing, so samples should be shipped promptly if IHC tests are anticipated. Histologic samples should be shipped in unbreakable containers and packed in a manner that prevents spillage during shipment. *Fixed tissues should be protected from freezing.*

Specific tissues collected at necropsy require additional attention. Because the GI mucosa decomposes rapidly, short sections of gut collected at necropsy must be opened lengthwise to allow adequate fixation. If spinal cord is to be submitted, the dura mater should be carefully incised lengthwise to permit more rapid penetration to the cord. Fixing the brain poses a special dilemma, especially if a neuroanatomic location of the lesion(s) within the organ could not be determined antemortem. Ideally, a whole, intact fixed brain is required for complete histopathologic analysis. Immersion of the brain for many days in a very large volume of formalin is required to adequately fix such a specimen, so brains are commonly transported in an only partially fixed state. If the specimen can be shipped by overnight delivery, it may be acceptable to send a chilled, carefully packaged, unfixed brain, which can then be processed at the diagnostic laboratory. Often, the brain is halved longitudinally and one-half sent unfixed (fresh), properly refrigerated, for microbiologic tests, while the other half partially fixes in transit. This method can prove unsatisfactory if a solitary unilateral lesion is involved. Slicing the brain into widths suitable for rapid fixation introduces considerable fixation

artifact and should be avoided if possible; fixing the intact/halved brain in a large volume of formalin for >24 hr is preferred.

Microbiology: Any specific agents that are of interest in the diagnostic investigation should be mentioned on the submission form; some agents have requirements (eg, anaerobic culture, special media) that would not be used in most laboratories unless the pathogen was cited as a differential diagnosis. Laboratory techniques and capabilities for microbiologic examination vary; available tests include bacteriologic culture, fungal culture, virus isolation, in-situ hybridization, a variety of PCR methods, fluorescent antibody tests, latex agglutination tests, Western blotting, ELISA, and many others. Most tests, including the newer molecular biology techniques, rely on either the growth/visualization of intact viable organisms or the detection of the nucleic acids and proteins of these pathogens. Therefore, unfixed specimens (tissue, fluid, etc) should be collected aseptically and shipped promptly to avoid degradation. If PCR testing is to be performed, it is particularly important to avoid cross-contamination between multiple animals in a submission; this applies to tissues, fluids, and even dissection instruments. Furthermore, swabs destined for PCR analysis should not be placed in agar or charcoal-based transport media. Calcium alginate swabs should be avoided. Instead, cotton or dacron swabs should be shipped in a tube with a few drops of sterile saline or viral transport media.

Some test protocols may permit pooling of organ specimens from an individual, but for the vast majority, it is preferable that each tissue be collected into separate sterile, clearly labeled bags or tubes for shipping. Gut samples must never be pooled in a container with other tissue samples. Tissues and fluids for most microbiologic assays may be frozen before shipment, but generally freezing is undesirable if samples can be chilled and delivered directly to the laboratory within 24 hr. Exceptions to this rule include analysis for certain toxins, such as those of *Clostridium perfringens* and *C botulinum*, in which degradation of the toxin must be prevented by prompt freezing after collection. Adequate refrigerant should be provided so that samples remain chilled (or frozen) until they reach the laboratory.

Toxicology: If a known toxin is suspected, a specific analysis should always be requested—laboratories cannot just

"check for poisoning." A complete description of clinical and epidemiologic findings may help differentiate poisoning from infectious diseases that can simulate poisoning. For a list of appropriate samples for many of the more common toxicities, see TABLE 1. The most critical samples to be collected are generally stomach contents,

liver, kidney, whole blood, plasma/serum, and urine, but exceptions exist, such as cerebral tissue for cholinesterase analysis. For some investigations, the diagnosis requires analysis of feed or water. If there is doubt about sample submission procedures, the laboratory should be contacted.

TABLE 1

GUIDELINES FOR SUBMITTING SAMPLES FOR TOXICOLOGIC EXAMINATION

Suspected Poison or Analysis	Specimen Required	Comments
Ammonia	Whole blood or serum Urine Rumen contents	Frozen Frozen Frozen (or may add 1–2 drops saturated HgCl ₂)
Anticoagulants (warfarin and related compounds)	Whole blood Liver Feed Stomach contents	Heparin or EDTA Refrigerated
Arsenic	Liver Kidney Urine Ingesta Feed	
Chlorates	Stomach contents Urine Feed	Frozen, in airtight container
Chlorinated hydrocarbons	Cerebrum Ingesta Body fat Liver Kidney	Use only glass containers Avoid contamination Refrigerated or frozen
Cholinesterase	Serum Cerebrum	Frozen
Copper (and Ni, Fe, Co, Cr, and Tl)	Kidney Liver Serum Feed Whole blood Feces	
Cyanide	Forage Whole blood Liver	Rush to laboratory or ship promptly, frozen in airtight container
Dicoumarol	Forage Liver	
Ethylene glycol	Serum Urine Kidneys	Fresh plus fixed in formalin

(continued)

TABLE 1

GUIDELINES FOR SUBMITTING SAMPLES FOR TOXICOLOGIC EXAMINATION (continued)

Suspected Poison or Analysis	Specimen Required	Comments
Fluorides	Bone Water Forage Urine	Best to send affected bone(s)
Herbicides (many)	Treated weeds Urine Ingesta Liver or kidney	
Ionophores	Feed Rumen contents Heart Skeletal muscle	Fixed in formalin Fixed in formalin
Lead (also Hg, Mo, Ni, and Tl)	Kidney Whole blood Liver Urine	Heparinized blood preferred
Mercury and molybdenum	Kidney Whole blood Liver Feed	See LEAD, above
Mycotoxins	Grain, forages Liver, kidney	Consult with laboratory personnel on specific tests
Nitrate	Forage Water Body fluids (eg, aqueous humor)	Refrigerated
Organophosphates (and carbamates)	Feed Ingesta Urine	Also send urine, blood, and stomach contents from clinically normal animals
Oxalates	Fresh forage Kidney	Do not macerate; freeze Fixed in formalin
Phenols	Gastric or rumen contents	In airtight container
Polychlorinated (and polybrominated) biphenyls	Fat Cerebrum Feed	
Rumen pH	Ingesta	Frozen
Selenium	Whole blood Feed Liver Hair clippings	Heparinized

TABLE 1

GUIDELINES FOR SUBMITTING SAMPLES FOR TOXICOLOGIC EXAMINATION (*continued*)

Suspected Poison or Analysis	Specimen Required	Comments
Strychnine (and some other convulsants such as bromethalin)	Liver Kidney Stomach contents	
Sulfates	Water Brain	Fixed in formalin
TDS (total dissolved solids)	Water	
Triaryl-PO ₄	Ingesta Feed	
Urea	Feed	See AMMONIA, above
Vitamin A (also D and E)	Liver Serum	Frozen
Vitamin D ₃ (rodenticides)	Kidney	
Zinc	Liver Kidney Serum	Use "trace minerals" tubes
Zinc phosphide	Liver Gastric contents	Frozen

Tissues or fluids for chemical analysis should be as fresh as possible and kept refrigerated. For some analyses, freezing is critical to prevent degradation of volatile chemicals, and in rare instances a chemical preservative is required.

If legal action is a possibility, all containers for shipment should be either sealed so that tampering can be detected or hand-carried to the laboratory and a receipt obtained. The chain of custody must be accurately documented.

If feed or water is suspected as the source of poisoning, samples of these and any descriptive feed tag should accompany the tissue samples. If at all possible, a representative composite sample of the feed should be submitted from the suspect lot or shipment. In some instances, if an adequate amount of involved feed is available, some of it may be fed to experimental animals in an effort to reproduce the signs and lesions seen in the field cases.

Hematology: Routine studies require anticoagulated whole blood and several blood smears. Blood smears should be prepared immediately after the sample has been collected to minimize cell deterioration. Anticoagulated blood should be kept

refrigerated; blood smears should not. EDTA is the anticoagulant of choice for a CBC because it best preserves the cellular components of the blood and prevents platelet aggregation. Blood for coagulation testing should be collected into a blue top tube, which contains sodium citrate. After mixing, the sample should be centrifuged for 5 min, and then plasma should be removed and transferred to a clean tube without anticoagulant. The plasma should be kept frozen until the time of analysis. Whole blood should not be frozen because this causes cell lysis and gross hemolysis, which interfere with testing.

Clinical Chemistry: Most clinical chemistry tests require serum, but an occasional test may require plasma. Anticoagulants present in plasma may interfere with tests; therefore, serum should always be submitted unless plasma is specifically requested. Because lipemia can interfere with a number of chemistry tests, dogs and cats should be fasted for 12 hr before samples are collected.

For serum samples, the blood should be drawn into a red top tube or a separator tube. The sample should be held at room temperature for 20–30 min to allow

complete clot formation and retraction. Incomplete clot formation may cause the serum to gel due to latent fibrin formation. The clot should be separated from the glass by gently running an applicator stick around the tube walls ("rimming"). The sample should then be centrifuged at high speed (~1,000 g; 2,200 rpm) for 10 min. Rough handling of the sample or incomplete separation of erythrocytes from serum may promote hemolysis, which can interfere with certain tests.

If the sample has been collected into a serum separator tube, centrifugation will cause a layer of silicon gel to lodge between the packed cells and the serum. The gel layer should be inspected to ensure the integrity of the barrier, and re-centrifugation is recommended if there is a visible crack in this layer. If a red top tube has been used, the serum should be removed and transferred to a clean tube. Serum should be refrigerated or frozen until analyzed.

Many commercial laboratories provide sample containers and mailers.

Serology: Serology generally requires serum, but plasma is often satisfactory. Samples should be collected as described for clinical chemistry tests and should always be free of hemolysis. In some instances, paired samples may be required for an adequate diagnosis. The acute sample should be collected early in the course of the disease and frozen. The convalescent sample should be collected 10–14 days later, and both samples should be forwarded to the laboratory at the same time.

Cytology: Air-dried smears are usually acceptable. Rapid air drying of smears minimizes cell distortion, thereby enhancing diagnostic quality. However, depending on the method of staining used, some laboratories prefer alcohol-fixed smears. Samples can be obtained by fine-needle aspiration or by scraping. Imprints (touch preparations) of external lesions can also be used, although these tend to have a greater degree of contamination. Aspirated material should always be smeared before air drying. Smears of fluid can be prepared using a traditional blood smearing technique. Highly cellular fluids may be smeared directly; fluids of low cellularity should be centrifuged to concentrate the cells. Thick material or viscous fluid is more readily smeared using a squash technique in which a second glass slide is placed over the aspirated material and then slid rapidly and smoothly down the length of the lower slide.

Blood or cytologic smears should never be mailed to the laboratory in the same package with formalin-fixed tissues because formalin vapors will produce artifacts in the specimen. Many laboratories now offer immunocytochemical testing, and proper handling of cytologic submissions is required for reliable results. Usually air-dried, unfixed smears will suffice, but in some instances shipping of samples in tubes containing a transport media is recommended.

Fluid Analysis: Analysis of various effusions and fluids usually includes determination of protein content, total cell count, and cytologic examination. Other tests may be performed depending on the source or appearance (eg, chylous fluid) of the effusion. A sample of effusion/fluid should be collected into an EDTA (purple top) tube for routine analysis. A second sample should be collected into a serum (red top) tube if any biochemical analyses (eg, triglyceride, cholesterol, lipase for chylous effusions) are to be performed or if a bacterial culture is desired (eg, joint fluid). These samples should be shipped chilled but not frozen. Smears for cytologic examination (*see above*) should be prepared from a drop of the fluid immediately after the sample has been collected to minimize cell deterioration and other *in vitro* artifacts. Samples of CSF should be collected into small EDTA tubes and *shipped immediately with high priority*; the cytologic value of CSF samples degrades rapidly and the low cellularity makes examination of direct smears unrewarding. If sufficient CSF is available, then a red top tube sample may be useful for serology or culture attempts.

Genetic Analysis: Tests based on the detection of specific genetic features range from karyotype analysis to the identification of specific genes. The laboratory offering the test should be contacted to determine the specifics of sample collection and handling; required samples range from hair to skin or blood. Many blood-based analyses require collection into yellow-topped acid-citrate-dextrose tubes and overnight shipment of the chilled tubes to the laboratory. Tissue samples for genetic analysis should be unfixed and shipped immediately after collection. As with most molecular techniques, aseptic collection and the prevention of cross-contamination between samples is critical for reliable test results.

DIAGNOSTIC PROCEDURES FOR THE PRIVATE PRACTICE LABORATORY

Numerous laboratory tests can be done in a private practice laboratory. Use of a commercial laboratory versus in-house testing should be evaluated to determine whether in-house testing is practical and economical. Because the availability of diagnostic laboratories and their reporting intervals may be problematic (eg, nights and holidays), performing some diagnostic screening tests in-house is often desirable. However, because the people performing these tests often have minimal technical training, quality control procedures must be rigorous. The time and care that must be devoted to quality control issues may preclude in-house testing in many practices. Errors may occur not only in testing procedures but also in sample collection and handling and in recording results.

Tests can be done using either manual or automated methods. Manual methods tend to be time consuming and are more subject to human error. Automated and semiautomated systems are available but are more expensive. Factors to be considered include instrument and reagent costs (including materials for calibration and quality control), availability of personnel training, technical support, and instrument maintenance and service. Although service contracts can cost up to 10% of the purchase price of an instrument, they are often cost-effective because of the expense of instrument repair.

CLINICAL BIOCHEMISTRY

Clinical biochemistry refers to the analysis of the blood plasma (or serum) for a wide variety of substances—substrates, enzymes, hormones, etc.—and their use in diagnosis and monitoring of disease. Analysis of other body fluids (eg, urine, ascitic fluids, CSF) is also included. One test is very seldom specific to one clinical condition, and basic checklists of factors affecting the most commonly requested analytes are given below. Thus, rather than six tests that merely confirm or deny six possibilities, a well-chosen group of six tests can provide information pointing to a wide variety of different conditions by a process of pattern recognition. Biochemistry tests should be accompanied by full hematology, because

evaluation of both together is essential for optimal recognition of many of the most characteristic disease patterns (*see p 1610*).

Before samples are collected, a list of differential diagnoses should already be established based on the history and clinical examination. Then, additional appropriate tests can be added to the basic panel below.

Making a diagnosis entails establishing a list of differential diagnoses based on the history and clinical examination. Based on this list, tests can be selected to include or exclude as many of the differentials as possible. Yet more tests may be necessary until only one of the original list remains to determine the diagnosis. If all differentials are excluded, then the list must be reevaluated. It is not good practice to order tests without a sensible differential list unless the animal presents without definitive clinical signs.

Basic Test Panel: Most veterinary laboratories offer a basic panel of tests, which represents a minimal investigation applicable to most general situations. For small animals, a typical panel includes total protein, albumin, globulin (calculated as the difference between the first two analytes), urea, creatinine, ALT, and alkaline phosphatase (ALP). In addition, a yellow color seen in the plasma should be considered an indication to measure bilirubin. This panel may be modified as appropriate for other species, eg, glutamate dehydrogenase (GDH) and/or γ glutamyl transferase (γ GT) are more appropriate "liver enzymes" for horses and farm animals, or it may be more appropriate to concentrate primarily on muscle enzymes (CK and AST) in athletic animals.

Total protein level increases due to dehydration, chronic inflammation, and paraproteinemia. It decreases due to overhydration, severe congestive heart failure (with edema), protein-losing nephropathy, protein-losing enteropathy, hemorrhage, burns, dietary protein deficiency, malabsorption, and some viral conditions (especially in horses).

Albumin level increases due to dehydration. It decreases due to the same factors as total protein, plus liver failure.

Urea level increases due to excess dietary protein, poor quality dietary protein, carbohydrate deficiency, catabolic states, dehydration, congestive heart failure, renal failure, blocked urethra, and ruptured bladder. It decreases due to low dietary protein, gross sepsis, anabolic hormonal effects, liver failure, portosystemic shunts (congenital or acquired), and inborn errors of urea cycle metabolism. Urea measurement is used especially to indicate renal disease and to a lesser extent liver dysfunction.

Creatinine level increases due to renal dysfunction, blocked urethra, and ruptured bladder. It decreases due to sample deterioration. Animals with a high muscle mass have high-normal creatinine concentrations, whereas animals with a low muscle mass have low-normal creatinine concentrations. Creatinine measurement is used especially for renal disease.

ALT is present in the cytoplasm and mitochondria of liver cells and, therefore, increases due to hepatocellular damage. It has a half life of 2–4 hr and rises higher than AST but recovers quicker. There are minor increases with muscle damage and hyperthyroidism.

ALP level increases due to increased bone deposition, liver damage, hyperthyroidism, biliary tract disease, intestinal damage, hyperadrenocorticism, corticosteroid administration, barbiturate administration, and generalized tissue damage (including neoplasia). The most common causes for an increase is raised levels of circulating steroids and biliary disease. The half-life is 72 hr in dogs but only 6 hr in cats. Levels in the cat are generally much lower than in the dog, and *any* increase in cats is considered significant. In dogs, ALP levels in the thousands of units are usually associated with increased steroid levels. ALP and ALT levels rarely rise above 1,000 units, even in severe liver disease.

GDH level increases in hepatocellular damage, particularly hepatic necrosis, in horses and ruminants.

γGT increases in longer-term liver damage; it is particularly useful in horses and ruminants.

CK, the classic “muscle enzyme,” increases markedly in rhabdomyolysis and aortic thromboembolism. Slight level increases are reported in hypothyroidism. ● Only a very small amount of muscle damage such as bruising or IM injections can result in high serum CK levels. In dogs and cats, unless investigating specific muscle disease, increased levels are generally of no clinical significance.

AST level increases in both muscle and liver damage but is of less value than ALT. The half-life is 5 hr in dogs and 77 min in cats. It is also reported to increase in hypothyroidism.

Most of the above parameters are associated with liver function/dysfunction and are frequently overinterpreted. In small animals, increases in ALT and ALP levels can reach four times normal and still be associated only with fatty change, a nonspecific finding and not, in most cases, a primary liver problem. Some laboratories also frequently receive liver biopsies from dogs that have significant increases in liver enzymes and bile acids >80 but that have normal histologic morphology. The reason for this is unknown.

In general, plasma enzyme levels decrease due to sample deterioration. Uncommonly, atrophy or fibrosis of an organ may result in unusually low plasma activities of the relevant enzymes.

Additional Tests: Further tests may be added to the basic panel, according to the principal presenting signs, to create panels for polydipsic animals, collapsing animals, etc. These panels are structured so that the patterns of abnormalities typical of all the likely differential diagnoses applicable to the situation can be discerned. For example, a polydipsia panel may add calcium, glucose, and cholesterol. Calcium allows recognition of hyperparathyroidism and other causes of hypercalcemia (which causes polydipsia and renal insufficiency), glucose may indicate diabetes mellitus and contributes to the pattern characteristic of hyperadrenocorticism, and cholesterol also adds to the appreciation of the “Cushing pattern.” Renal failure is covered by the tests already included in the basic panel. In contrast, in a panel for a “collapsing animal,” calcium and glucose may be added to screen for hypocalcemia or hypoglycemia. Sodium and potassium are included to screen for hypoadrenocorticism or hypokalemia. Analytes that might be considered for incorporation in such expanded profiles are described below.

Sodium level increases due to Conn syndrome (hyperaldosteronism), restricted water intake, vomiting, and most causes of dehydration. It decreases due to hypoadrenocorticism, loss of any high-sodium fluid such as some forms of renal disease, and insufficient sodium provision during IV fluid therapy.

Potassium level increases due to hypoadrenocorticism and severe renal failure (especially terminal cases). It

decreases due to Conn syndrome, chronic renal dysfunction, vomiting, diarrhea, and insufficient potassium provision during IV fluid therapy. Congenital hypokalemia occurs in Burmese cats.

Chloride level increases in acidosis, and in parallel with increases in sodium concentration. It decreases in alkalosis, vomiting (especially after eating), and in association with hyponatremia.

Total CO₂ (bicarbonate) level increases in metabolic alkalosis and decreases in metabolic acidosis. It is less useful to assess respiratory acid/base disturbances.

Calcium level increases due to dehydration (which is also associated with increased albumin), primary hyperparathyroidism (neoplasia of parathyroid gland), primary pseudohyperparathyroidism (neoplasms producing parathormone-related peptide [PRP], usually perianal adenocarcinoma or some form of lymphosarcoma), bone invasion of malignant neoplasms, thyrotoxicosis (uncommon), and overtreatment of parturient paresis. It decreases due to hypoalbuminemia, parturient paresis, oxalate poisoning, chronic renal failure (secondary renal hyperparathyroidism), acute pancreatitis (occasionally), surgical interference with parathyroid glands, and idiopathic (autoimmune) hypoparathyroidism.

Phosphate level increases due to renal failure (secondary renal hyperparathyroidism). Decreases are seen in some downer cows and as part of the stress pattern in horses and small animals.

Magnesium level increases are rarely seen, including during acute renal failure. It decreases in ruminants due to dietary deficiency, either acute (grass staggers) or chronic, and diarrhea (uncommon).

Glucose level increases due to high-carbohydrate meals, sprint exercise, stress or excitement (including handling and sampling stress), glucocorticoid therapy, hyperadrenocorticism, overinfusion with glucose/dextrose-containing IV fluids, and diabetes mellitus. It decreases due to insulin overdose, insulinoma, islet cell hyperplasia (uncommon), acetonemia/pregnancy toxemia, acute febrile illness, and idiopathic (in certain dog breeds).

β-Hydroxybutyrate level increases in diabetes mellitus. It is a major component of ketoacidosis and as such is also increased in acetonemia/pregnancy toxemia and extreme starvation. It can be measured in both blood and urine.

Bilirubin level increases due to fasting (benign effect in horses and squirrel

monkeys, may be caused by hepatic lipidosis in cats), hemolytic disease (usually mild increase), liver dysfunction, and biliary obstruction (intra or extrahepatic).

Theoretically, hemolysis is characterized by an increase in unconjugated (indirect) bilirubin, whereas hepatic and post-hepatic disorders are characterized by an increase in conjugated (direct) bilirubin; however, in practice this differentiation is unsatisfactory. Better appreciation of the source of the jaundice is gained from bile acid measurements.

Bile acid levels increase when hepatic anion transport is impaired, usually during liver dysfunction (bile acids are more sensitive than bilirubin to hepatic impairment) and in the presence of a portosystemic shunt (congenital or acquired). The latter condition is characterized by a marked increase in bile acid concentration after feeding, from a fasting concentration that may be normal. It also increases in bile duct obstruction; very little increase is seen in feline infectious peritonitis or mild cases of hepatic lipidosis. Very high levels can sometimes be seen without structural histologic changes. The reason for this is not known.

Cholesterol level increases due to fatty meals, hepatic or biliary disease, protein-losing nephropathy (and other protein-losing syndromes to some extent), diabetes mellitus, hyperadrenocorticism, and hypothyroidism. It decreases in some cases of severe liver dysfunction and occasionally in hyperthyroidism.

Lactate dehydrogenase is a ubiquitous enzyme with a number of isoenzymes; electrophoretic separation of isoenzymes is necessary to locate the source of increased activity. It is therefore of very limited value in general clinical practice.

Sorbitol dehydrogenase level increases in acute hepatocellular damage in horses but is a very labile analyte.

α-Amylase level increases in acute pancreatitis but in dogs is also increased in chronic renal dysfunction. It is therefore of limited use in the diagnosis of pancreatitis. Pancreatic lipase immunoreactivity is now the test of choice for diagnosis of pancreatitis in dogs and cats. Amylase is not a useful indicator of pancreatitis in cats.

Lipase level increases in acute pancreatitis in dogs (longer half-life than amylase) and also occasionally in chronic renal dysfunction. Lipase (routine assay) is not a useful indicator of pancreatitis in cats.

Immunoreactive trypsin (trypsin-like immunoreactivity) level decreases

in exocrine pancreatic insufficiency in dogs. It will also increase (irregularly) in pancreatitis.

Tests for Pancreatic Disease:

Pancreatitis: Serum amylase and lipase activities have been used for several decades to diagnose pancreatitis in both people and dogs. Unfortunately, neither of these tests is both sensitive and specific for pancreatitis in dogs. In one study, significant serum amylase and lipase activities remained after total pancreatectomy, indicating there are sources of serum amylase and lipase activity other than the exocrine pancreas. Also, clinical data suggest a specificity for pancreatitis of only ~50% for both of these markers. Many nonpancreatic diseases, such as renal, hepatic, intestinal, and neoplastic diseases, can lead to increases in serum amylase and lipase activities. Steroid administration can also increase serum lipase activity and cause variable responses in serum amylase activity. Thus, in dogs, measurement of serum amylase and lipase activities are of limited usefulness for diagnosis of pancreatitis. Serum amylase and/or lipase activities that are 3–5 times the upper limit of the reference range, in animals with clinical signs consistent with pancreatitis, are suggestive of such a diagnosis. However, it is important to note that ~50% of dogs that fulfill these criteria do not have pancreatitis. In cats, serum amylase and lipase activities are of no clinical value for diagnosis of pancreatitis. Although cats with experimental pancreatitis can show an increase in serum lipase activity and a decrease in serum amylase activity, these changes are not consistent in cats with spontaneous pancreatitis. In one study of 12 cats with severe forms of pancreatitis, not a single cat had serum lipase or amylase activity above the upper limit of the reference range.

Serum trypsin-like immunoreactivity (TLI) concentration measures mainly trypsinogen, the only form of trypsin circulating in the vascular space of healthy individuals. However, trypsin, if present in the serum, is also detected by these assays. Serum TLI concentrations can be measured by species-specific assays that have been developed and validated for both dogs and cats. In healthy animals, serum TLI is low, but during pancreatitis an increased amount of trypsinogen leaks into the vascular space, which can lead to an increase in serum TLI concentration. Trypsin that has been prematurely activated may also contribute to this increase. However, both trypsinogen

and trypsin are quickly cleared by the kidneys. In addition, any prematurely activated trypsin is quickly removed by proteinase inhibitors, such as α_1 -proteinase inhibitor and α_2 -macroglobulin. In turn, α_2 -macroglobulin-trypsin complexes are removed by the reticuloendothelial system. Thus, the serum half-life for TLI is short, and a significant degree of active inflammation is required to increase serum TLI concentration. Because of the limited sensitivity of serum cTLI and fTLI concentrations for canine and feline pancreatitis, respectively, and because only a limited number of laboratories measure these assays routinely, serum TLI concentration is of limited usefulness for diagnosis of pancreatitis in dogs and cats.

Pancreatic lipase immunoreactivity (PLI) concentration measures the concentration of classical pancreatic lipase in the serum. This is in contrast to serum lipase activity, which measures the enzymatic activity of all triglyceridases present in the serum, regardless of their cellular origin. Assays to measure PLI in canine (cPLI) and feline (fPLI) serum have been developed and validated and are commercially available. Serum PLI is highly specific for exocrine pancreatic function. Also, serum PLI is far more sensitive for diagnosis of pancreatitis than any other diagnostic test currently available.

A patient-side semiquantitative assay for diagnosis of canine pancreatitis is also available. A test spot that is lighter in color than the reference spot suggests that pancreatitis can be excluded. A test spot darker in color than the reference spot raises the suspicion of pancreatitis and should prompt the clinician to measure a serum cPLI concentration in the laboratory.

Other tests for diagnosis of pancreatitis in dogs and cats have been evaluated, including plasma trypsinogen activation peptide (TAP) concentration, urine TAP concentration, urine TAP:creatinine ratio, serum α_1 -proteinase inhibitor trypsin complex concentration, and serum α_2 -macroglobulin concentration. However, none has been shown to be of clinical usefulness.

Exocrine Pancreatic Insufficiency: In the past, several fecal tests have been used to diagnose exocrine pancreatic insufficiency (EPI). Microscopic fecal examination for fat and/or undigested starch or muscle fibers are at best useful to suggest maldigestion. However, in light of wide availability of tests to diagnose EPI, microscopic fecal examination is no longer justified. Fecal proteolytic activity had been used to

diagnose EPI in small animals for several decades. Most of these methods, particularly the radiographic film clearance test, are unreliable. One method, which uses pre-made tablets to pour a gelatin agar, is considered most reliable. However, false-positive as well as false-negative results have been reported. The clinical use of fecal proteolytic activity is limited to species for which more specific assays to estimate pancreatic function are not available and in areas where the more accurate and sophisticated tests are not available.

Serum TLI concentration is the diagnostic test of choice for EPI in both dogs and cats. Assays for TLI measure trypsinogen circulating in the vascular space. In healthy animals, only a small amount of trypsinogen is present in serum. However, in dogs and cats with EPI, the number of pancreatic acinar cells is severely decreased. Serum TLI concentration decreases significantly and may even be undetectable. The reference range for TLI in dogs is 5.7–45.2 mcg/L with a cut-off value of ≤ 2.5 mcg/L, considered diagnostic for EPI. Similarly, the reference range for TLI in cats is 12–82 mcg/L, with a cut-off value of ≤ 8 mcg/L, considered diagnostic. Rarely, animals with serum TLI concentrations below the cut-off value for EPI do not have clinical signs of EPI. This is probably because of the functional redundancy of the GI tract. At the same time, many dogs and cats with chronic diarrhea and weight loss have mild decreases in serum TLI concentration. Most of these animals have chronic small-intestinal disease and should be investigated accordingly. However, a small number of these dogs and cats may have EPI. If there is no evidence of small-intestinal disease in such patients, a trial therapy with pancreatic enzymes and reevaluation of serum TLI concentration after 1 mo is indicated.

PLI is also highly specific for exocrine pancreatic function and could be used to diagnose EPI. However, initial studies showed there is a small degree of overlap in serum PLI concentrations between healthy dogs and dogs with EPI, making the measurement of PLI slightly inferior to that of TLI for accurate diagnosis. In view of these findings, PLI assays for both dogs and cats have been optimized toward higher concentrations, and the current assays are no longer suitable for diagnosis of EPI in dogs or cats.

A fecal canine elastase concentration assay has been developed and validated but is inferior to the widely used TLI measurement.

Handling of Samples: Most biochemistry tests can be performed on either serum or heparinized plasma. A few (eg, insulin) require serum, whereas potassium is best measured on heparin plasma separated immediately after collection. Glucose measurement requires fluoride/oxalate plasma. Suitable collection tubes with and without anticoagulant are available commercially. Plastic tubes are satisfactory for blood in anticoagulant, but clotted blood must be collected either into glass tubes or plastic tubes specially coated to prevent the clot from adhering to the vessel walls.

Samples for biochemical analysis should be separated as soon as possible after collection to minimize artifacts caused by hemolysis and leakage of intracellular fluid components (eg, potassium) out of the cells. Samples in anticoagulant may be centrifuged immediately, but clotted samples need at least 30 min to allow the clot to form. Fluoride/oxalate samples hemolyze very readily because the cells can no longer respire, so timely separation is especially important. Proprietary gels or plastic beads assist with separation, and these may be incorporated into the collection tube or added before centrifugation.

Larger bucket-type centrifuges will accept almost any type or size of tube, but the rotors require careful balancing. They should be spun at 3,000 rpm for 10 min. Dual-purpose, high-speed microhematocrit centrifuges are favored for in-practice use, because they separate samples more quickly and the same machine can be used to measure PCV. However, they can handle only a limited range of small-volume tubes.

Some “gel-tube” products may provide a permanent separation of serum or plasma; otherwise, this must be separated into a fresh tube. The new tube must be adequately labeled. Samples may then be sent to a professional laboratory or analyzed in the practice.

Point-of-Care Tests: A number of biochemical analytes may be estimated in the practice without the need for large analytical instruments.

Total protein level is measured by refractometry, using the same instrument as is used to measure urine specific gravity, provided the instrument has a total protein scale. It is also valid for protein measurement of ascitic and pleural fluids. The readout may be in g/dL, in which case multiplying the result by 10 will yield the SI unit of g/L.

Urea level may be estimated by chromatographic reaction strips, which correlate well with standard laboratory methods. A rapid whole-blood color comparison strip is also available, but these read only up to ~20 mmol/L and are thus of limited use. A dedicated reflectance meter for urea estimation is not available.

Glucose meters for use on whole blood are widely available for home use by human diabetic patients. These yield acceptably accurate results on animal blood, although an unexpected hypoglycemia should be confirmed by a professional laboratory. Fresh whole blood may be used, but fluoride blood or plasma is the preferred sample if analysis is not immediate.

Ketone levels may be estimated on either urine (preferred sample) or plasma/serum. This can be achieved by using the ketone patch of a urine dipstick, giving a qualitative result. However, there are a number of point-of-care instruments for measurement of blood glucose and ketone levels, including specifically β -hydroxybutyrate.

Triglyceride levels may be visualized in a plasma or serum sample as lipemia. If the milkiness rises to the top of the tube on storage, chylomicrons are present. Otherwise, the milkiness is caused by triglycerides. This is a qualitative judgment but is nevertheless useful, especially in equine patients.

Bilirubin level may also be appreciated by eye in most species. Equine and bovine plasma is normally yellow, which makes determination problematic, but in other species, any yellow color is abnormal and indicates an increased bilirubin level. Visual assessment of the depth and shade of color may provide additional information.

Other point-of-care tests include **C-reactive protein** as a marker for inflammation and **cardiac troponin** as a marker for cardiac muscle damage.

For emergency in-clinic use, the most important analytes beyond these simple basics are sodium and potassium. A dedicated ion-specific electrode meter is the best way to measure these. Instruments are available that can analyze whole blood, although great care must be taken to avoid artifacts due to unappreciated hemolysis. Critical care meters are also available that can estimate a variety of analytes, including glucose, urea, and electrolytes; however, these have not been extensively validated on nonhuman blood, and results should be interpreted with caution.

The Practice Laboratory: Extending in-practice analysis beyond these emer-

gency basics requires a dedicated instrument capable of measuring multiple analytes. Two types are available—those based on transmission/absorbance photometry (wet chemistry) and those based on reflectance photometry (dry-reagent chemistry). Transmission/absorbance photometry is the reference method on which all reference values and interpretive guidelines are based. Reflectance photometry methods do not always compare well with the reference method and are best confined to simpler tests such as glucose and urea. For wider applications, such as enzyme analysis, wet chemistry instruments are preferred.

In-clinic analysis is inevitably more expensive than the same investigations done by a professional laboratory, and the range of analytes available is more restricted. Additionally, the level of accuracy or reliability is likely to be lower. Therefore, it is still best practice to regard in-practice analysis as an interim emergency investigation, with the results to be confirmed as appropriate by a professional laboratory. Detailed case laboratory evaluation of nonemergency patients is best referred to a professional laboratory from the outset, for reasons of cost, accuracy, range of analytes available, and the assistance of the clinical pathologist in interpretation of the results.

If in-clinic analysis is to be relied on for general case laboratory evaluation, meticulous attention must be paid to quality assurance. Samples of known composition must be run at least daily for each analyte, in both normal and pathologic ranges; unless these are within the tolerance limits, no patient samples should be tested. Participation in an external quality assessment program is also strongly recommended. Employing a trained technician will address some of these issues but has implications for availability of results during off hours and holidays. The veterinarian in charge of the laboratory is responsible for all the results issued and incurs a legal liability to prove accuracy and reliability. If these cannot be guaranteed to the same standard as a referral laboratory, then results should not be relied on without external confirmation.

CLINICAL MICROBIOLOGY

In-house microbiology can be a valuable asset to practitioners, providing quick results with minimal investment. Expensive equipment and materials are not usually necessary for recovery of common aerobic or

facultatively anaerobic bacterial pathogens, such as *Staphylococcus* spp, *Streptococcus* spp, and coliforms. Although microbiologic media is not difficult to prepare, it may be more convenient to purchase from a scientific supply house. Most bacteria will grow readily on standard media (blood agar and MacConkey agar plates) when incubated aerobically. Basic equipment should include an incubator, refrigerator, Bunsen burner or portable gas torch, and microscope with low, high, and oil immersion objective lenses. Materials should consist of inoculating loops, prepared microbiologic media, microscope slides, Gram-stain reagents, 3% hydrogen peroxide, oxidase reagent, microbial identification systems, and a current veterinary microbiology textbook.

Specimen Selection and Collection:

Although it is not always easy to obtain optimal specimens when working with animals, certain practices can ensure the best possible specimen under the circumstances. Application of the following principles should result in acceptable specimens that produce high-quality microbiology results: 1) Specimens must be obtained aseptically from a site that is representative of the disease process. 2) Swabs are the most common specimen collected, but they are generally not the specimens of choice, because they may become contaminated with commensals during the collection process and they provide a small sample volume. Swabs are most useful to obtain specimens from skin pustules, ears, conjunctiva, deep within draining tracts or wounds, soft-tissue infections, or the reproductive tract. 3) A sufficient quantity of material should be collected to permit adequate examination. 4) Specimens must be collected at the proper time in the disease process and before initiation of antimicrobial therapy to maximize pathogen recovery. 5) If specimens are not immediately cultured after collection, they should be refrigerated.

Specimen Processing: Microbiologic testing should include both direct and microscopic examination and culture of the specimen. Gram-stained smears should be examined using oil immersion to determine the correct reaction. Generally, both solid (agar) and liquid (broth) media should be inoculated. Solid media permit colony isolation, rough bacterial quantitation, and selection or differentiation of normal flora from potential pathogens, whereas broth media allow for recovery of small numbers of organisms.

Clinical specimens should be inoculated onto both general purpose and selective media to maximize bacterial recovery. Plates containing trypticase/tryptic soy agar with 5% sheep blood are the most widely used types of general purpose media. Selective and/or differential media include MacConkey agar (gram-negative bacteria), mannitol salt agar (staphylococci), and phenylethyl alcohol agar (gram-positive bacteria). Microbiologic media should be stored in the refrigerator but allowed to warm to room temperature before inoculation.

Transfer of specimens to plated media depends on the type of specimen. Liquid specimens are inoculated by use of a sterile syringe or pipette. Swabs are generally plated directly by rolling the swab over an area ~2 cm in diameter. Feces are inoculated by dipping a swab into the specimen. Surgical biopsy specimens may be touched directly to the agar surface.

Bacterial identification methods depend on obtaining isolated colonies. The most common technique to achieve isolation is to streak plates using a wire loop. After the specimen has been inoculated onto a plate, a wire loop is flamed, cooled, and passed at a 90° angle several times through the initial area of inoculation. The plate is rotated 90°, the loop is flamed and cooled, and the process is repeated three more times. This results in four quadrants on the plate, which enable quantitation of the relative numbers of bacteria present in a given sample after colonies appear.

After inoculation, plates and tubes should be labeled and placed in an incubator set at 35°–37°C. Plates are incubated with their lids down to prevent condensed water from dropping down from the lid onto the agar surface, which can result in confluent bacterial growth.

Bacterial Identification: The first step in culture evaluation is the visual examination of plated media. Most bacteria produce visible colonies in 24 hr, although some require 48–72 hr. Inspection includes examination of colonial morphology, noting both the types and numbers of colonies and any hemolytic reactions on blood-based agar. Further classification is based on the presence or absence of growth on differential or selective media.

After the evaluation of plated media, examination of Gram stains made from each different colony type is performed. Those reactions, combined with colonial morphology, may allow for the presumptive identification of organisms. If more than

one colony type is present, subcultures of each are made. A single colony is streaked to a plate of nonselective medium. This will ensure a pure culture of the unknown organism, which is required for biochemical characterization and identification.

Several microbial identification systems are commercially available. Systems may be manual or automated. Each usually contains a complete package for identification of a particular group of organisms. There are specific systems for staphylococci, streptococci, corynebacteria, nonfermenting gram-negative rods, and *Enterobacteriaceae*. All are useful to conduct a wide variety of biochemical tests simultaneously. Most manual systems consist of plates or strips made up of a series of wells or cups that contain test substrates. A pure culture of the unknown organism in suspension is added to the test wells. The strips are incubated aerobically at 37°C for 24–48 hr. The wells are viewed for colorimetric changes, and a biocode is generated from scoring the test results. This numeric code is compared with those in the system database to obtain an identity for the test organism. Most systems are adequate for identification of common, rapidly growing aerobic to facultatively anaerobic veterinary pathogens.

Antimicrobial Susceptibility Testing:

Antimicrobial susceptibility testing is indicated when the susceptibility of a pathogen cannot be reliably predicted based on the clinician's experience or the identity of the pathogen, or if the antimicrobial agent of choice would not be acceptable for therapeutic use. There are two common procedures to determine the antimicrobial susceptibility of bacteria that are able to grow aerobically within 24 hr, and both have been accepted by the Clinical and Laboratory Standards Institute (CLSI). The first procedure is qualitative and is based on the agar disk diffusion method of Bauer and Kirby. The second procedure is quantitative and involves dilutions of antimicrobial agents, which are tested either in liquid or solid agar media. The latter is referred to as the minimal inhibitory concentration test.

The agar disk diffusion method is more widely used to test the common, rapidly growing aerobic to facultatively anaerobic pathogenic bacteria and lends itself better to in-house testing. The Bauer-Kirby method is based on the diffusion of an antimicrobial agent impregnated within a paper disk through an agar medium. Briefly, a suspension of actively growing test

organism is standardized to a turbidity equivalent to 0.5 on the McFarland scale. Within 15 min of standardization, a sterile swab is dipped into the bacterial suspension and a dry Mueller-Hinton agar plate is inoculated by streaking the swab over the entire surface three times. To ensure an even distribution of the inoculum, the plate is rotated ~60° each time. Antimicrobial disks are placed on the plate and gently pressed down to ensure their close contact with the agar surface. Inverted plates are placed in an incubator at 35°C. Plates are examined after 18 hr of incubation. Zones of complete inhibition are measured in millimeters. The zone sizes around each drug are compared with those published by the CLSI in document VET01-S2: *Performance Standards for Antimicrobial Disk and Dilution Susceptibility Tests for Bacteria Isolated from Animals* to make an interpretation of susceptible, intermediate, or resistant for each agent tested.

Reliable antimicrobial susceptibility testing results can only be obtained by following standardized procedures set forth in CLSI document VET01-A4: *Performance Standards for Antimicrobial Disk and Dilution Susceptibility Tests for Bacteria Isolated from Animals, Second Informational Supplement*. Any procedural deviation may lead to erroneous results. It is imperative to properly store antimicrobial susceptibility test disks and test media and to ensure quality control for each test. Any clinic that does not regularly perform testing on a weekly basis may wish to use a veterinary diagnostic laboratory for this procedure instead.

CYTOLOGY

Cytology is a useful clinical tool for investigation of disease processes, and the techniques and their interpretation have developed into an entire discipline. This discussion is a brief guide to enable practitioners to prepare samples and undertake basic interpretation; it refers mostly to small animals, but the basic principles apply to all species.

Cytology should be considered a guide. Characteristics of the cells may not be sufficient in many instances to yield a definitive diagnosis or indicate the probable behavior of the lesion. These may require examination of the overall architecture of the tissue, for which cytology is not appropriate. If complex, expensive, or life-threatening therapy is being considered, then the diagnosis should if possible be confirmed by histology.

Techniques

Full cytologic interpretation requires a good quality sample. A substantial minority of samples collected by practitioners are unsuitable for full interpretation. The technique appears to be simple, but consistently obtaining good-quality samples requires practice. If samples are sent to a laboratory for interpretation, sending more than one is recommended. In addition, staining and examining one of the preparations in-house helps to monitor the quality of the samples taken and make a provisional diagnosis. This requires a good staining technique and a good quality microscope with a range of objectives, including oil immersion.

Staining: The stains and techniques used for cytology preparations in a practice setting are the same as those used for hematology preparations. The traditional stains for cytology preparations are modified Wright stain (Wright-Giemsa) and May-Grunwald Giemsa. Over the past few years, good-quality rapid Romanowsky stains have been developed for cytology and hematology and are often used by veterinary diagnostic laboratories. Many different brands of rapid stain have been developed, so trying a number of products to see which stain is best suited to a practice is recommended. Poor preparations are not always the fault of the collection technique; the stain may be the problem. Stains deteriorate with use and require regular renewal. Many slides can be adjusted by returning a finished stained slide to the stain for deeper color reaction, or if overstained, can have some color removed by placing the slide in alcohol. Formalin-fixed cytology preparations must be stained with either H&E or Papanicolaou stain. If samples are sent to a laboratory for interpretation, the submission form should indicate whether formalin has been added.

Fine-needle Aspiration: The aim of fine-needle aspiration is to obtain a high cell harvest with minimal artifactual damage or blood contamination. The basic sampling kit consists of 21- and 25-gauge needles and 3-, 5-, and 10-mL syringes. Precise technique and choice of equipment depends on physical characteristics of the lesion and whether blood contamination is a problem.

The basic technique uses a 25-gauge needle and a 10-mL syringe. The needle is inserted into the lesion and repeatedly redirected to sample a number of areas while applying a small amount of suction on

the syringe. Suction is released before withdrawing the needle. If suction is continued on withdrawal, the cell sample is violently sucked into the barrel of the syringe, causing cell rupture. Sample size is often very small and may be present only within the lumen of the needle and not in the syringe. When the sample has been obtained, the syringe is removed, filled with air, reattached, and used to gently express the sample onto a clean, dry, glass slide. Expressing the sample forcefully will rupture cells. Another slide is placed on top of the sample and pulled lengthways to spread the sample to a monolayer. Additional pressure should not be applied, because this also may cause rupture of the cells. Thicker areas are not a concern; the edges will often be thin enough to examine individual, nonoverlapping cells. The sample should be air dried as quickly as possible to reduce the effects of shrinkage; a hair dryer can be used for this purpose, but heating the sample must be avoided.

This technique can be adapted to different situations. If blood contamination is a problem, the size of the syringe and amount of suction can be reduced or the syringe removed altogether. This is particularly a problem with bone marrow aspiration but is common with all cytology samples and is thought to be due to excessive suction on the syringe. If blood contamination is unavoidable, the blood can be centrifuged. However, if the sample is directly smeared, a feathered edge should be examined, because this is where the heavier cells from the tissue tend to congregate. Blood contamination can often be decreased with the use of a very fine needle (25 gauge); this increases the chance of collecting enough cells for interpretation.

An alternative technique uses a needle without a syringe; no difference in the cell harvest between these two techniques has been shown. The needle is inserted without the syringe and repeatedly redirected to sample different depths and directions within the lesion. The cells are detached by the cutting edge of the needle and enter the needle lumen by capillary action. After withdrawal of the needle, a syringe containing air is reattached and used to gently express the sample. This technique is also particularly useful to sample fragile cells, such as lymphoid cells from lymph nodes. A far better cell harvest is obtained from splenic lesions with this technique than by applying suction. In addition, there is greater sensitivity in placement of the needle, which is especially useful for small lesions.

Certain tissues tend to give a very low cell harvest. These are usually composed of mesenchymal cells (connective tissue) that tightly adhere to each other and therefore do not exfoliate easily. For these lesions, a larger bore needle and increased suction may be necessary. However, a needle with a bore >21 gauge tends to provide a tissue core more suitable for histologic interpretation than cytology.

Impression Smears: Impression smears are often used for ulcerated surface lesions. They are of limited value, because they usually sample only the surface inflammatory exudate and rarely include cells from deeper tissues. A better use of this technique is at the time of biopsy to allow an immediate assessment of the lesion before fixation and processing of the tissue sample. The cut surface of the excised sample is blotted a number of times to remove surface blood and serum, and the dried surface is applied to a clean, dry slide with gentle pressure. A number of areas can be prepared on a single slide. The preparations should be quickly air dried and then stained.

Body Fluid Evaluation: Once a body fluid (eg, urine, pleural or peritoneal fluid) is obtained, a cytospin preparation is by far the best method of cell concentration. However, few practices have access to a cytospin, so centrifugation of the preparation and sampling of the centrifuged sediment is the usual method of cell concentration. Once the slide has been prepared, it should be rapidly air dried before staining.

If the fluid is to be sent to a laboratory, adding a few drops of formalin (the concentration is not critical) helps preserve cells and prevent bacterial overgrowth

during transit. Severe bacterial overgrowth obscures the cells, and their metabolic products tend to destroy cells in cytology preparations. This is particularly useful for bronchoalveolar lavage samples and urine, which often contain infectious agents and are prone to bacterial contamination at sampling. The laboratory must be advised of the presence of formalin, which excludes the use of Romanowsky stains. Adding EDTA to help preserve cytology samples is often recommended, but the effect is minimal.

Cells in CSF samples degenerate very quickly and are usually present in very low numbers. Cytospin preparations are almost essential for CSF examination; this can usually be achieved only in a reference laboratory. The addition of a few drops of 10% formalin preserves the cells in CSF very well during transit.

Interpretation of Cytology Samples

Cytology interpretation can be guided by an algorithm that also covers the common questions asked by clinicians. From a clinical viewpoint, it is often not necessary to complete all stages of this algorithm. For example, a simple differentiation of inflammation from neoplasia may be sufficient to allow a decision on the next stage of case management. Full cytology interpretation may require the services of a diagnostic laboratory, and a definitive diagnosis often requires histopathology. Some lesions cannot be definitively diagnosed by cytology. If in doubt or if the cytologic interpretation does not correlate with the clinical picture, histology is essential for full interpretation. Whenever the diagnosis is in doubt, biopsy is indicated.

Algorithm to interpret cytology samples.

Inflammation: Recognition of basic inflammatory cells—neutrophils, eosinophils, lymphocytes, macrophages, and plasma cells—is essential for interpretation of cytology samples. Some tumors contain a large number of inflammatory cells, but these are very uncommon, even when there is tumor necrosis. The presence of only inflammatory cells in a sample usually indicates a primary inflammatory lesion. Ulceration produces inflammation on the surface of neoplastic lesions, but even in this case the inflammatory cells typically do not extend deeply into the underlying neoplasm. A small percentage of mast cell tumors, however, are composed almost entirely of inflammation, hemorrhage, and edema with only a small number of mast cells. These can be difficult to identify even by histology.

Neutrophils: These are the first cells to arrive in an area of inflammation, and they continue to be attracted to the site as long as the inflammatory stimulus lasts. Large numbers of neutrophils indicate acute inflammation and often are accompanied by smaller numbers of macrophages. This pattern is most often caused by infection or foreign body reaction, including furunculotic reactions directed against hair and keratin embedded in the soft tissue. If fluids are not examined immediately, bacteria, if present, will begin to proliferate, but phagocytosis of bacteria does not occur after sampling. Therefore, if the bacteria are truly pathogenic, they should be within the cytoplasm of the phagocytic cells. The cells' cytoplasm may contain RBCs, tissue debris, or foreign material.

Macrophages: Macrophages arrive at a site of inflammation within 2–3 hr and are not necessarily an indicator of chronicity, although they often increase with time. They phagocytize bacteria and also larger structures, such as fungi, cellular debris, and foreign material. These cells are often associated with tissue destruction.

Macrophages come from circulating monocytes and have variable morphology. In the tissue, the cytoplasm greatly enlarges over time and usually becomes vacuolated. The nuclei become rounded. If a macrophage exhibits vacuolation or phagocytosis, it is often described as activated. They can be multinucleated, especially with foreign body reactions and in longstanding lesions. Under certain circumstances, they may become epithelioid. These cells have oval or round nuclei and small, often indistinct, nucleoli. Their cytoplasm is expanded but uniformly stained and not

vacuolated. They can look epithelial, and great care must be taken when interpreting such cells. However, they do not normally form clusters, which is a key factor in differentiation from epithelial cells.

Macrophages are almost always seen in bronchoalveolar lavage fluid (they come from the alveoli) and body cavity fluids (part of the modification process), joints (a normal component but increased in disease), and cyst contents (a nonspecific reaction).

Eosinophils: Eosinophils have segmented nuclei and eosinophilic cytoplasmic granules. They vary slightly between species and are generally slightly larger than neutrophils. In cytology preparations, it can occasionally be difficult to distinguish poorly stained eosinophils from neutrophils, because the granules can become indistinct and the cytoplasm of degenerating neutrophils become more acidic, giving a more eosinophilic staining reaction. They are often seen in association with mast cells. Eosinophils are associated with allergies and also are prominent in parasitic diseases, superficial cutaneous viral infection in cats, and fungal infections. They are the predominant cell type in specific eosinophilic conditions such as eosinophilic granuloma in cats (rarely in dogs), canine eosinophilic folliculitis and furunculosis, and eosinophilic collagenolytic granuloma in horses. Some cases of canine cutaneous mast cell tumors have a very high proportion of eosinophils and very few mast cells (<5% of cases).

Of the most commonly encountered veterinary species, rabbits and guinea pigs have inflammatory cells equivalent to neutrophils in other species, but have eosinophilic cytoplasmic granules. These are called heterophils. They can be difficult to distinguish from eosinophils. The cellular equivalent to neutrophils in birds and reptiles are also heterophils with eosinophilic granules.

Lymphocytes: Lymphocytes are usually small with very little cytoplasm and smudged chromatin with no nucleoli. The almost-round nuclei are similar in size to those of red cells. RBCs are often present in cytology preparations, where they can be used as a comparative and absolute scale. RBCs vary slightly with species; in dogs, RBCs are ~7 microns in diameter. Medium and large lymphocytes, which have a slightly more open chromatin pattern and more cytoplasm, can also be seen in inflammatory processes. Along with plasma cells, lymphocytes are part of the chronic

inflammatory response and tend to arrive in tissue a few days after the acute inflammation has begun. However, they are not specific for a particular stimulus and are mostly small lymphocytes. If mostly medium to large cells are present, lymphoma is a possibility. However, even large lymphoblastic cells can be seen in low numbers in inflammatory processes. Normal and reactive lymphocytes in body fluids often appear larger than the same cells from soft tissue.

Multinucleated Cells: These cells are large and have larger numbers of nuclei with one to three small nucleoli and vacuolated cytoplasm. They develop from macrophages (see above) and tend to appear late in the course of inflammation. The cytoplasm should be examined for the presence of fungal organisms and for foreign material. These cells are usually seen in small numbers mixed with other inflammatory cells as part of a granulomatous reaction. Multinucleated cells are much less specific in birds and reptiles, in which they are common in many focal inflammatory lesions, irrespective of cause, and can appear quite early in the inflammatory process.

Fibroblasts: Fibroblasts are not inflammatory cells, but they are frequently seen in association with inflammation. They will proliferate as part of the repair reaction associated with any tissue damage and appear in an inflammatory lesion after ~2 days. Classically, fibroblasts and fibrocytes are elongated cells with pointed tails of cytoplasm. They have round or oval nuclei, indistinct nucleoli, and moderate amounts of uniform, pale blue-staining cytoplasm. The cytoplasmic boundaries are indistinct, giving a "wispy" appearance. When fibroblasts are aspirated from tissue, the cells often become round and lose their spindle shape, but a small number, especially cells in groups, retain their elongated shape. Reactive fibroblasts cannot be definitively distinguished cytologically from low-grade spindle cell tumors. If found in association with inflammatory cells, spindle cells are most often reactive. If found in large clumps with no apparent stimulus, they are more often neoplastic (but neoplasia cannot be excluded). Because fibroblasts and fibrocytes are the principal connective tissue cell, they are tightly adherent to each other, and cell harvest tends to be low.

Neoplasia: Inflammatory lesions are characterized by cells from different

populations. The presence of cells that are predominantly of the same population indicates normal tissue, hyperplasia, or neoplasia. Ideally, the first stage in evaluation of a cytologic sample for neoplasia is to determine the tissue type from which the cells have come. If this is not possible, it is necessary to simply determine the likely behavior of the cells. This can often be done without specifically identifying the cell type. The following checklist includes features that can be examined to determine tissue type and likely behavior of the lesion: 1) cell numbers, 2) cell distribution within the smear, 3) cell shape, 4) nucleus:cytoplasm ratio, 5) pleomorphism (both nuclear and cytoplasmic), 6) number, shape, and size of nucleoli, and 7) cytoplasmic content such as melanin, metachromatic granules, fat, etc. Classification of the cell type and likely behavior may require a tissue biopsy. With few exceptions, histology will be necessary for a definitive diagnosis and is always necessary to assess mitotic index and to grade a tumor.

There are three basic tissue types: epithelial, mesenchymal (supporting or connective tissue), and round cells.

Epithelial Cells: Epithelial cells are round, cuboidal, or polygonal and tend to adhere tightly to each other and exfoliate in clusters or sheets. They have a sharp cytoplasmic outline and exfoliate in moderate numbers. Cells with more than one nucleus are uncommon.

Mesenchymal Cells: Mesenchymal cells are tightly adherent and usually exfoliate in low numbers as single cells or small aggregates. They are classically spindle shaped but usually round up and become

Within the usual blood contamination, there are cells that are well separated and nonadherent; this is typical of round cell tumors. Courtesy of Abbey Veterinary Services.

plump when removed from the body, particularly when they are lying singly within the smear. The spindle shape is often more apparent in small aggregates. They tend to appear "wispy" because of indistinct cytoplasmic boundaries. Binucleate cells are not uncommon.

Round Cells: Round cells have little or no adherence in the body. They typically exfoliate in large numbers and lie individually in the smear without clumping. Cells of this category include mast cells, lymphocytes, histiocytes, plasma cells, and cells of transmissible venereal tumors.

Tumor Evaluation: To distinguish benign from malignant tumors, the amount of variation in certain characteristics within the cell population must be assessed. In general, the more malignant the cell, the less differentiated it becomes and the more variation there is in the cell morphology. Benign tumors have cells that are often uniform in size with a uniform nucleus:cytoplasm ratio; they strongly resemble or are identical to the cell of origin. The more malignant the cells become, the more variation is seen in these criteria. Nuclear criteria are the major indicators of malignancy.

Criteria for malignancy include the following: variation in cell size and shape, increased cell exfoliation, increased nuclear size, increased nucleus:cytoplasm ratio, variation in nuclear size and an increase in multinucleated cells, increased mitosis with abnormal mitotic figures, a coarse and often clumped chromatin pattern, altered shape of the nucleus due to close approximation of a nucleus from an adjacent cell (nuclear moulding), and large and often multiple nucleoli of irregular and abnormal shape. There are a number of exceptions to these indicators; in such situations, histology is essential for full interpretation.

The following are some exceptions to the rules of interpretation:

Thyroid carcinomas usually have fairly uniform, well-differentiated cells. A diagnosis of carcinoma can be made simply on the size of the mass in dogs (tumors >3 cm are automatically considered malignant) but not in cats. Major features of malignancy, such as capsular, soft-tissue invasion and vessel invasion, can only be identified histologically. Other tissues in which it may be impossible to differentiate benign from malignant cells include **apocrine gland carcinomas**, **basal cell tumors**, **melanomas**, and proliferative lesions of the liver.

Unlike most malignant tumors, **lymphoma** is commonly characterized by a uniform population of cells that are larger than normal lymphoid cells. Therefore, variation in morphology is not necessary for a diagnosis of malignancy with this tissue type. If there is marked variation and small lymphocytes are present, then that is more typical of hyperplasia.

Some normal structures, such as hepatoid glands, have more than one cell type (reserve and terminal cells) and can therefore show variation in morphology, and benign tumors of hepatoid glands can have a similar mixture. Nuclear morphology, however, maintains benign features.

Many **mammary tumors** can show marked variation in cell morphology but histologically would be classified as benign. Indicators of mammary tumor behavior are architectural features, such as local tissue invasion and invasion of vessels. These cannot be assessed using cytology. These exceptions often make cytologic interpretation unreliable, particularly for these types of tissues.

Most **spindle cell tumors** do not metastasize but are locally aggressive and often difficult to remove. The criteria for malignancy are often less important with respect to the behavior of these tumors than for the epithelial tumors.

Common Cytology Results: Some specific features of cytology preparations can provide a more accurate interpretation of the sample. Listed below are some common results and their interpretation.

Mature Fat Cells: Mature fat cells are seen in benign lipomas and mature body fat. It is not possible to differentiate these

These typical balloon-like fat cells are characteristic of benign lipoma and mature body fat. Both involve the same cells and cannot be distinguished on cytology. Courtesy of Abbey Veterinary Services.

cytologically. Fat cells are mesenchymal cells, and because they tend not to exfoliate well, they are usually present in low numbers. If a sample has come from the center of a nodular mass, fat cells are diagnostic for lipoma. These clear-staining, balloon-like cells are often in clusters, folded, and overlapping.

Spindle Cells: It is usually not possible to differentiate reactive spindle cells from those of spindle cell neoplasia. Indicators of neoplasia include absence of a reactive stimulus, such as inflammation or hemorrhage, and a higher cell population with more numerous and larger clumps of cells. Greater variation in cell morphology indicates more aggressive behavior. When removed from their tissue, they often round up and can be mistaken for round cells, but there are usually some distinctly spindle cells in most preparations.

Keratin: Keratin includes nucleated and terminally differentiated non-nucleated squamous epithelial cells. Keratin can be a contaminant from the surface of the skin of the animal or the skin of all handlers of the sample and is a common artifact. It can also be sampled from cutaneous keratin-filled cysts, which are always benign and very common, particularly in dog skin. Large, densely packed clumps of keratin in restricted areas in the center of the slide suggest that keratin is not an artifact but has been sampled from the lesion.

Blood: Blood is a common artifact of fine-needle aspiration but can also come from blood-filled spaces in tissue. These can be non-neoplastic, such as hematomas, aneurysms, or severe bruising, or neoplastic lesions such as hemangiomas and hemangiosarcomas. The presence of spindle cells does not adequately differentiate neoplastic from non-neoplastic causes of hemorrhage (see above). Spindle cells produce the neoplastic blood vessels in hemangiosarcomas, but especially in young dogs, they can occasionally produce a very cellular capsule to a soft-tissue hematoma. The capsule contains very active fibroblasts, but they are not neoplastic. Blood that has come directly from the vascular system normally contains significant numbers of platelets. Using a 25-gauge needle can help decrease blood contamination. Blood is almost always seen in aspiration from parenchymatous organs, such as the liver, spleen, kidneys, and bone marrow.

No Cells: Lack of cells is a common problem of fine-needle aspiration. If the technique is practiced properly, absence of cells can indicate mesenchymal cell

proliferation (including lipomas), because these structural cells within the body are tightly adherent cells that do not exfoliate well.

Cells with Cytoplasmic Granules:

The most important type among cells with cytoplasmic granules is the **mast cell**, given that mast cell tumors are common in dogs. These are medium-sized cells with round nuclei. With Romanowsky stains, the granules are dark blue or purple, small (about the size of bacteria), and usually found in large numbers in the cytoplasm. Less-differentiated mast cells have fewer granules. Cytology cannot be used to grade mast cell tumors; grading always requires histology, because it does not depend on only cell morphology. The cells are fragile, and often there are large numbers of granules in the background that have been released from damaged cells. In dogs, eosinophils are often present and very occasionally can be the dominant cell type; however, they are less common in other species. Mast cell tumors in horses have similar cytology to those in dogs, but in cats the cells in mast cell tumors are often smaller, more uniform, and have less distinct granulation.

Thyroid cells can also have dark granules, usually blue or black. These tyrosine granules are very small, low in number, and can be difficult to see. Larger black granules are associated with **melanomas**. Cytology cannot differentiate benign from malignant melanomas; however, melanomas on haired skin in dogs are usually benign and those on nonhaired areas, such as the lips, feet, and mouth, are usually malignant. Basal cell tumors also often contain cells with melanin, especially in cats. These tumors are usually benign and cytologically can sometimes be difficult to distinguish from melanomas. Melanin can also be seen in **macrophages (melanophages)**, sometimes in large amounts, but it is usually in much larger clumps within the cytoplasm rather than fine granules that are seen in melanocytes. Very fine magenta granules can sometimes be seen in **osteoblastic cells** from osteosarcoma. Golden, granular material accumulates in the cytoplasm of macrophages when there has been hemorrhage into soft tissue (hemosiderophages). **Liver cells** can sometimes contain bile, which stains very dark, and occasionally long, thin strands of dark material can be seen where canaliculi have become filled with bile.

Cells with Cytoplasmic Vacuoles:

A large, single vacuole is seen in fat cells. In normal or benign cells, the nuclei are small and often indistinct, and the cells are often folded like a collapsed ball. Smaller cells with larger, more prominent nuclei and some cytoplasm in addition to clear, often small vacuoles are more suggestive of malignancy.

Cells with multiple, small vacuoles with a foamy appearance include macrophages, sebaceous glandular cells, and salivary cells. It can be very difficult to differentiate these; the site and other clinical features can be a deciding factor in interpretation.

Differentiation of Round Cell Tumors:

Round cell tumors include mast cells, plasma cells, lymphocytes, histiocytic cells, and transmissible venereal tumor cells.

Mast cells have distinctive granules within the cytoplasm and are usually easily identified; if they are the dominant cell type, this is diagnostic for a mast cell tumor. In rare cases, mast cells can have few or no granules in the cytoplasm. **Lymphoid cells** classically have a very high nucleus:cytoplasm ratio; few other cells have this feature. Neoplastic, lymphoid cells are medium size to large, with a nucleus at least 1.5 times the size of an erythrocyte. Nucleoli are often multiple, sometimes quite prominent. However, the rare cases of small-cell lymphoma have cells indistinguishable from normal lymphocytes.

Cells of a **histiocytoma** (Langerhans cells) are not especially histiocytic cytologically. They are round cells with a small to moderate amount of pale-staining cytoplasm. They are fairly uniform and have nuclei that are eccentric within the cell. Nucleoli are indistinct. True **histiocytic cells** are slightly more problematic to interpret. These are part of the cell line that includes the antigen-presenting cells, such as macrophages and Langerhans cells, but can range from inflammatory and reactive cells to highly malignant round cell tumors. They tend to be larger than the other round cells with more cytoplasm, sometimes are vacuolated, and can have oval or indented nuclei. Infiltrates of histiocytic cells are often problematic, even with a full-tissue biopsy examination, and always require histologic examination to assess behavior.

Neoplastic plasma cells include cells of **myeloma**. These are usually well differentiated and have most of the characteristics of normal plasma cells. When neoplastic, they are found in large numbers with few other cell types present. Benign nodular proliferations of plasma cells, **plasmacytomas**,

show more marked pleomorphism and often differ markedly from normal plasma cells. Many have a slightly histiocytic appearance, and these can be difficult to distinguish cytologically. These cells have a round nucleus and a coarse chromatin pattern, which sometimes becomes clumped around the nuclear membrane. The nucleus is often eccentric with an intensely basophilic cytoplasm and paranuclear pale Golgi zone.

Cells of **transmissible venereal tumors** tend to have a moderate amount of cytoplasm (more than found in lymphoblasts), often with small vacuoles. Nuclear chromatin is coarse, with one or two fairly prominent nucleoli. Mitotic figures are often numerous. Unlike most cytology preparations of neoplastic lesions, they tend to have moderate variation in the nucleus:cytoplasm ratio.

Cytology of Specific Sites:

Lymph Nodes: Normal, hyperplastic, and early neoplastic lymph nodes have a mixed population of cells. Cells are predominantly small lymphocytes with variable numbers of medium and large lymphoid cells and some plasma cells. A uniform population of cells indicates neoplasia. Lymph node aspirates often have a population of cells that are much paler staining and larger, with some cells completely losing their cytoplasm. These cells are in varying stages of degeneration and should be ignored. Size in comparison with RBCs is useful. Normal mature lymphocytes or small neoplastic lymphocytes (rare) have nuclei the same size as RBCs. However, neoplastic lymphoid cells have nuclei at least 1.5 times the diameter of RBCs. Lymphomatous lymph nodes may still contain a significant number of normal lymphoid cells. The proportion of smaller mature lymphocytes must then be compared with the larger immature cells to differentiate hyperplasia from neoplasia. The proportion considered significant varies, but in general, most cytologists consider a diagnosis of lymphoma when immature cells are >50% of the cell population. Some cytologists require a higher percentage of immature cells, particularly if there is only one lymph node enlarged. If there is doubt, a biopsy should be performed. Histopathologic confirmation of diagnosis is essential if therapy for lymphoma is considered and is always needed for full grading.

Submandibular lymph nodes are often difficult to assess. They drain the buccal and

nasal areas and are subject to strong antigenic stimuli. They frequently undergo hyperplasia, often histologically atypical, especially in cats. Cats also develop unusual neoplastic conditions affecting this node, such as the T cell-rich B-cell lymphoma and Hodgkin-like lymphoma, both of which have a majority of normal lymph node cells. For these reasons, great care must be taken in the interpretation of lesions involving the submandibular lymph nodes, because false-negative and false-positive results for neoplasia are not uncommon.

Aspirates from suspected enlarged submandibular lymph nodes often yield only large foamy cells, which are salivary cells. This result can be due either to sampling error or to hypertrophy of the salivary gland in cases of sialoadenosis. The cause of sialoadenosis is not understood, but a significant minority of submandibular aspirates contain only these cells.

Body Cavity Fluids: Meaningful analysis of fluids from body cavities requires total protein (measured with a handheld refractometer), total cell count, and a differential of cell types present (see TABLE 2). Pure transudates are rare, because they rapidly become modified by leakage of fluid from lymphatics or blood vessels and attraction of mixed inflammatory cells. Transudates attract activated macrophages with varying numbers of nondegenerate neutrophils. The lymphocytes that may also be present are classified as small, but most look slightly larger than circulating lymphocytes and are part of the reactive process of the fluid in the body cavity. In addition, when fluid accumulates in the body cavity, the lining mesothelial cells proliferate and are shed into the fluid. These cells are large, often multinucleated, vary in appearance, and often are seen in groups with large nucleoli. They sometimes form grape-like clusters with a narrow, pale space between the cells. These features are usually considered to be associated with malignancy, but in this case, the cells are simply reactive and not neoplastic. Care must be taken to differentiate these

mesothelial cells from neoplastic cells within the body fluid. A small number of these cells typically have a corona around the cytoplasmic envelope (giving a fuzzy outline); this is a distinguishing feature of mesothelial cells.

Mesothelial cells can be present in very large numbers, especially in pericardial fluid. Malignant mesotheliomas are rare in domestic species, but it is not possible to differentiate neoplastic from reactive mesothelial cells on cytologic examination. The degree of polyploidy is not a distinguishing feature.

Mixed inflammatory cells increase in number as a transudate becomes modified and are present in large numbers in an exudate. Mesothelial cells would be expected in this type of sample, and it can therefore be useful to look for a second population when checking for neoplasia. Smoothly demarcated aggregates of atypical cells with no narrow spaces between the cells may indicate a second population of carcinoma cells.

Tracheal or Bronchoalveolar Lavage (BAL): Respiratory epithelial cells are seen in BAL from healthy and diseased animals. The epithelial cells may retain their original structure with a ciliated surface and basal nuclei, but they often appear round with indistinct cilia.

Macrophages are usually the dominant inflammatory cell type in BAL from healthy animals. These come from deep in the alveoli and are part of the normal defense mechanisms. They greatly increase with fluid accumulation in the lung (eg, cardiovascular insufficiency) and in inflammatory conditions, where they are accompanied by other inflammatory cells. Debris, foreign material, hemosiderin, RBCs, and microorganisms can sometimes be seen in the cytoplasm of these cells. Macrophages containing hemosiderin in people are called heart failure cells, but their cause is less specific in domestic species. There are increased numbers of macrophages in many subacute and chronic lung disorders.

TABLE 2 CHARACTERISTICS OF TRANSUDATES AND EXUDATE

	Total Protein (g/dL)	Cell Count (cells/mL)
Transudate	<2.5	<1,500
Modified transudate	2.5–7.5	1,000–7,000
Exudate	>3.0	>7,000

In healthy dogs and cats, **neutrophils** contribute <5% of cells in BAL preparations. Neutrophils are nonspecific inflammatory cells in the respiratory system and do not necessarily indicate infection. They can be the most numerous cells in an inflammatory reaction, even in cases of allergy. However, when neutrophils are present, the cytoplasm should always be examined carefully for the presence of any infectious agent. Bacteria can also sometimes be seen in the extracellular parts of the smear, but extracellular bacteria are often contaminants from the pharynx.

Great care must be taken to differentiate **eosinophils** from neutrophils in BAL preparations because the granules are often faint and difficult to identify. Eosinophils can comprise up to 5% of cells in BAL from healthy dogs but may reach 10% in healthy cats. Eosinophils that comprise >10% of cells indicate an allergic respiratory disease, although lungworms and heartworms can also cause this reaction. With lungworm infestation, larvae are sometimes present as large coiled structures.

Nucleated and nonnucleated **squamous cells** are commonly seen in BAL preparations and are often associated with bacteria on the cell surface. This indicates contamination from the pharynx. Bacteria are normal inhabitants of the pharynx, in particular *Simonsiella*, which are very large, ladder-like organisms. Their presence confirms contamination from the pharynx. If bacteria are present along with squamous epithelial cells, it may not be possible to conclude whether the bacteria are from the respiratory tree or the pharynx. Bacteria in the cytoplasm of neutrophils confirms a significant infection.

Synovial Fluid: Full examination of synovial fluid should include protein content, mucin clot formation, viscosity, cell count and differential, and direct cytologic examination. It is usually not feasible to perform all of these tests in a practice setting, but cytologic examination and physical examination can usually give a good estimate of the results of most of these tests. Cytology, therefore, is the most useful single test in synovial fluid examination.

Sampling technique requires the following equipment: a 3-mL syringe, a 21- or 25-gauge needle, clean glass slides, and various collection tubes (plain, EDTA, and heparin). This technique always requires a degree of sedation, and a sterile technique is essential. Each joint has a recommended site for aspiration (beyond the scope of this discussion) and generally requires slight flexion or hyperextension. The needle

attached to the syringe is slowly advanced into the joint space and, taking care not to scratch the articular surface, gentle suction is applied. Normal joint fluid is viscous and sticky and of small volume. The volume of fluid, however, depends on the size of the animal, the joint sampled, and the degree of effusion into the joint. When sample size is sufficient, it is essential to release the suction on the syringe before withdrawing the needle.

Sample handling is critical; because many tests can be performed on synovial fluid and cytology is the most important, sometimes the sample volume is so small that no other test is possible. Therefore, a plain smear should always be made and quickly air dried as soon as the sample is obtained. Most tests can be performed on samples without anticoagulant (a plain red-topped tube), or the sample can be left in the sampling syringe. However, blood contamination, hemothrosis, and inflammatory effusion introduce fibrin into the joint, and the sample may clot. Placing part of the sample into an EDTA tube can prevent this, but EDTA can interfere in the mucin clot test and, for this reason, a heparinized sample may also be necessary.

Results of cytology preparations can indicate the number of cells present, the type of cell and the differential, the presence of tumor cells, and the presence of bacteria. They can also give an indication of viscosity. In fluid of normal or increased viscosity, cells tend to align in rows in the direction of the smearing; this is described as windrowing.

In healthy animals, **cell counts** vary widely (eg, 0–4,400/mL in dogs), but they are usually very low. Counts >500/mL in dogs generally indicate a significant increase. Normal synovial fluid contains ~2 cells/high-powered field (400× magnification). In the vast majority of cases where there is an increased cell content, cell numbers are either low (up to 4 or 5 cells/high-powered field) in degenerative joint disease or very high in septic or autoimmune arthritis. Intermediate equivocal results are extremely uncommon.

Cell types include joint mononuclear cells, which are a mixture of circulating monocytes, tissue macrophages, and synovial lining cells. It is not possible, or even necessary, to differentiate these cells, because they all have a similar morphology and all react to similar stimuli. Cytoplasmic vacuolation of these cells, and especially the presence of phagocytosis of debris or RBCs, indicate activation, a feature not seen in

normal joint mononuclear cells. In degenerative joint disease, synovial fluid usually contains only macrophages, occasionally with extremely low numbers of neutrophils.

Hemorrhage is common in synovial preparations but is frequently an artifact. True hemarthrosis provides a synovial fluid sample that is uniformly contaminated with blood at the time of sampling. If the blood contamination occurs at the very end of the sampling procedure with clear fluid initially, this is most likely artifact. In addition, in true hemarthrosis, RBCs may be seen in the cytoplasm of macrophages. Artifacts blood contamination will also introduce WBCs, such as neutrophils, making interpretation of inflammatory cells in the sample difficult, although blood contamination still gives only a low cell number.

Neutrophils are present in large numbers in both septic arthritis and autoimmune joint disease. These two conditions can usually be differentiated by the clinical history. In septic arthritis, bacteria are sometimes found within the cytoplasm of phagocytic cells. The absence of bacteria, either within cytology preparations or by culture, does not exclude bacteria as a cause of arthritis. False-negative results for bacteria are not uncommon.

Lymphocytes are often present in very small numbers in inflammatory processes but are not specific for a particular cause.

Osteoclasts are very occasionally seen when there has been erosion of the articular cartilage with exposure of the underlying bone.

Neoplastic cells in joint fluid are rare, although joints can be the site of both primary and secondary tumors.

Macrophages increase with any damage to a joint, especially in cases of degenerative joint disease. Cytoplasmic vacuolation of these cells, and especially the presence of phagocytosis of debris or RBCs, indicate macrophage activation, a feature not seen in normal joint mononuclear cells. In degenerative joint disease, synovial fluid often contains only macrophages.

Nasal Cavity: The cytology of nasal flush preparations is similar to that seen with BAL preparations. A small number of respiratory epithelial cells are usually flushed out along with exudate. A predominance of eosinophils may indicate inhaled allergens, parasites, or fungi and may occasionally indicate bacteria or neoplasia. The presence of eosinophils in the nasal cavity therefore is less indicative of a specific process than in some other sites, eg, the trachea or bronchi.

Neutrophils are the most common exudative cell but, as with BAL, often indicate secondary infection. In the case of intranasal neoplasia, cells with neoplastic characteristics (*see* p 1601) may be present, but absence of these cells does not exclude neoplasia. Only a minority of neoplastic processes erode the overlying respiratory epithelium and allow exfoliation of neoplastic cells.

Similarly, absence of fungal hyphae within the preparation does not exclude fungal infection. Unless fungal plaques are sampled directly for both cytology and culture, false-negative results are common. Viral inclusions are rarely seen.

Vaginal Cytology: This can be used to identify the various stages of the canine estrous cycle, but results must be interpreted in conjunction with the animal's behavior. A sample of exfoliated cells is obtained from the vaginal vault cranial to the urethral orifice with a cotton-tipped swab or glass rod. Cells are gently rolled onto a glass slide, air dried, and stained. Features to be identified include neutrophils, bacteria, RBCs, and the types of epithelial cells. Epithelial cells (in increasing order of differentiation) are parabasal, small and large intermediate cells, and superficial cells. Parabasal cells are small, with central round nuclei, indistinct nucleoli, a relatively narrow band of cytoplasm, and a nucleus:cytoplasm ratio of ~1:1. Small intermediate cells have a similar nucleus but a much larger amount of cytoplasm. Large intermediate cells have a similar nucleus with very large amounts of cytoplasm and an angular, irregular outline. Superficial cells also have large amounts of cytoplasm, but their nuclei are pyknotic (small and contracted) or absent.

The stages of the estrous cycle change gradually. If a preparation does not conform exactly to a specific part of the cycle, judgment must be made regarding what stages are present. In **proestrus**, all types of epithelial cells are present along with neutrophils, RBCs, and mucus. As proestrus progresses, the epithelial cells increasingly approach terminal differentiation (superficial cells), and neutrophils slowly decrease. Bacteria are often present in large numbers. In **estrus**, >90% of epithelial cells are superficial cells, with no background mucus. There are large numbers of bacteria, but no neutrophils. In **diestrus**, parabasal and intermediate cells are >80% of the total epithelial cells. Variable numbers of neutrophils and bacteria are present but usually fewer than in proestrus. It can be difficult to differentiate some stages of

proestrus from diestrus. In **anestrus**, parabasal and intermediate cells predominate. Neutrophils and bacteria are rare. RBCs do not help differentiate the stages of estrus.

Cerebrospinal Fluid: Interpretation of CSF cytology is difficult, because it can be hard to obtain enough well-preserved cells for examination before the sample deteriorates. Cell counts in normal CSF are low (0–5 cells/ μ L in dogs and 0–8 cells/ μ L in cats). However, there is a large variation in cell counts between individuals; counts can also vary between cisternal and lumbar taps in the same individual. Because the albumin level of CSF is ~20% of that found in serum, the cells that are present rapidly degenerate. Cell counts should ideally be done and morphology examined within 1 hr of collection.

Because of the low cell numbers, the use of an automated cell counter is usually not appropriate. A hemocytometer can be used for cell counts, and a cytocentrifuge for cytology preparations. A simplified sedimentation technique (description of which is beyond the scope of this discussion) to concentrate cells onto a slide is suitable for practice use. The presence of more than one or two nucleated cells in a plain smear of CSF should be considered potentially significant.

In CSF, an increase in nucleated cells is called **pleocytosis**. There is tremendous variation and overlap in both the degree of pleocytosis and the types of cells present in both infectious and noninfectious conditions in the CNS. Interpretation should be integrated with the other clinical details of the case. If neutrophils and/or macrophages are present, the cytoplasm of the cells should be searched for bacteria and fungi. The absence of organisms or pleocytosis does not exclude infection, and noninfectious conditions in the CNS can also produce a neutrophilic pleocytosis.

Apart from lymphoma, it is rare to find neoplastic cells in CSF. If noninflammatory cells are present in the CSF, they should be interpreted using the basic principles detailed above.

Urine Cytology: Urine can be examined as a wet preparation or as a dried cytology smear. Because of the absence of staining in a wet preparation, these are better limited to examination for crystals and RBCs. Although nucleated cells may be seen, in most cases they cannot be identified and are better examined using a dried cytology smear.

There are at least 10 common forms of urinary crystals. Identification is not discussed here but may be readily accomplished by use of good reference illustrations. (See *also* UROLITHIASIS, p 1525.)

Because cells in urine rapidly degenerate, particularly if bacteria are present, centrifuged preparations of urine samples should be examined rapidly after sampling. If this is not possible, boric acid is often added to urine to prevent degeneration and bacterial overgrowth, although its effect may be very limited. If a delay between sampling and examination is likely, a better preservation method is the addition of a few drops of formalin; however, the traditional Romanowsky stains cannot then be used. H&E stain is a better alternative for formalin-fixed samples.

Normal urine usually has very few nucleated cells. Single urothelial cells are occasionally present. Squamous epithelial cells are also seen in urine and come from the terminal urethra, vagina, vulva, and preputial epithelium. Squamous metaplasia of bladder epithelium after chronic inflammation is very rare.

Neoplastic cells in urine samples are almost always epithelial. They are rounded polygonal cells, often clumped, with marked variation in morphology, especially the nucleus:cytoplasm ratio. Uniform cells are more likely to be normal. Mildly pleomorphic cells can be associated with hyperplasia (eg, some cases of polypoid cystitis).

The inflammatory cells seen in cystitis are almost exclusively neutrophils. Eosinophils are seen in some rare, specific inflammatory conditions, but macrophages are very uncommon even in chronic conditions. By far the most common cause of inflammation is infection, so the cytoplasm of the neutrophils should be examined carefully for bacteria. It is very uncommon to see a significant neutrophil component accompanying neoplasia or calculi.

RBCs are commonly seen with neoplastic and inflammatory diseases of the bladder but are also often seen without an indication of other pathology. This can be a sampling artifact but is also a common finding in cases of interstitial cystitis. In cats, this term is often used synonymously with feline urologic syndrome, but interstitial cystitis also is seen in dogs and people, suggesting other unknown pathogenic factors that can cause this condition. Persistent hematuria without cytologic evidence of neoplasia or inflammation may indicate interstitial cystitis.

(See *also* URINALYSIS, p 1615.)

Liver Cytology: Although cytology is a popular method to investigate liver disease, there is disagreement on its usefulness. Blood contamination is found in most samples and may overshadow inflammatory infiltrates by introducing circulating WBCs. Diagnosis of many hepatic diseases relies on architectural features and the distribution of the changes within the liver rather than on the morphology of individual cells. Finally, in some hepatic disorders, hepatocytes proliferate without significant changes in their individual morphology (see below). These factors limit the amount of information that can be obtained from cytology of liver tissue.

Sampling methods are similar to those used for other organs. Sampling is usually performed under guidance of ultrasound, but blind sampling can be performed at the tenth intercostal space at the level of the connection of rib to rib cartilage. Bleeding during this procedure is not a significant risk.

In the healthy liver, hepatocytes are plump, polygonal rounded cells with a diameter of 25–30 microns. Nuclei are central and round with a single large, prominent nucleolus. A few cells are binucleated. There is a large amount of blue-staining cytoplasm that usually appears granular.

Changes in the metabolism of liver cells can be seen within the cytoplasm. The presence of numerous small, discrete vacuoles or one large vacuole indicates accumulation of fat. This has several potential causes and is prominent in feline hepatic lipidosis syndrome, starvation, pregnancy, and diabetes mellitus. Enlarged hepatocytes with a pale granular-staining cytoplasm but no discrete vacuoles are characteristic of excess glycogen storage. This is most often caused by increased levels of circulating steroids.

Bile stasis and pigment accumulation (eg, iron) can also be assessed by examination of the cytoplasm. Hepatocytes normally accumulate lipofuscin pigment, noted as small, fairly uniform, dark-staining granules, whereas bile and often hemosiderin tend to appear as slightly larger dark-staining bodies within the cytoplasm. Bile accumulation within the canaliculae (canalicular plugs) can also occasionally be seen. These appear as black ribbons on the surface of hepatocytes.

Cytologic interpretation of inflammation is difficult because of the inevitable blood contamination of samples. Inflammation should be considered significant only if it is present within clusters of hepatocytes.

Although the individual inflammatory cells can be recognized, it is not possible to indicate which part of the liver is principally affected. Neutrophils can be seen in diffuse hepatitis and also in more focal cholangitis. Small, mature inflammatory lymphocytes are usually seen in periportal inflammatory conditions, such as lymphocytic pericholangitis in cats and chronic active hepatitis in dogs. Macrophages can also be seen in the chronic inflammatory conditions and also in certain infections. Phagocytic cells should be investigated for the presence of organisms within the cytoplasm, but this is uncommon in liver disease.

Primary proliferative nodular hepatocellular lesions include regenerative hyperplasia, nodular hyperplasia, adenoma (hepatoma), and hepatocellular carcinoma. Biliary proliferations can appear as cysts, adenomas, or carcinomas. Bile duct cells tend to be smaller than hepatocytes with less cytoplasm. They are cuboidal or low columnar cells that occasionally produce tubular structures within cytology samples. The cytoplasm is also more uniformly pale staining and not significantly granular. Nucleoli are smaller and less distinct. Significant cell harvest from cystic bile ducts is uncommon because most of these lesions are simply cystic space rather than cellular. If a significant number of biliary epithelial cells are obtained, neoplasia is most likely. However, malignant bile duct cells are more commonly uniform in size and shape and, therefore, do not always show the morphologic features usually associated with malignancy.

Hepatocellular proliferation is a difficult area of interpretation, because hepatocytes in benign proliferative lesions are very similar to those in well-differentiated carcinomas and indeed often cannot be differentiated even from normal hepatocytes. Only in cases with poorly differentiated pleomorphic cells can an adequate interpretation of malignancy be made. The benign and non-neoplastic proliferations always have the same morphology as normal hepatocytes. Therefore, false-negative results for proliferative lesions within the liver are common. Cytology is thus of limited value for nodular hepatocellular lesions.

Cytology can be a useful technique for diagnosis of round cell tumors in the liver. Even with severe inflammatory lesions, lymphocytes are present in low numbers and are generally small, mature lymphocytes. A large population of medium and large lymphoid cells indicates lymphoma. No other condition will give this result.

The other common round cell tumor that can affect the liver (particularly in cats but also occasionally in dogs) is mast cell tumor. The granules within mast cells are metachromatic, facilitating diagnosis. Aspirates of normal liver may contain a few mast cells, but in neoplasia they are usually present in large numbers. If other cells are obtained from cytology preparations, they should be interpreted using the principles described above.

Kidney Cytology: Normal renal aspirates have almost a pure population of renal tubular cells. These are uniform, medium-sized cells of ~17–20 microns with central nuclei, small indistinct nucleoli, and a moderate amount of pale-staining cytoplasm. In cats, lipid droplets within the cytoplasm are a common, normal feature. The cells can be present either singly or in clusters and can occasionally be seen as tubular structures. They sometimes contain small, dark granules within the cytoplasm.

Renal lymphoma is the most common neoplastic disease of the kidney in cats and dogs. Because the cells are usually widely distributed within the tissue, false-negative results with cytologic examination are uncommon. Diagnosis can be made using the criteria described above. Primary renal tumors are uncommon.

Cystic lesions include renal cysts, most commonly seen in cats but also occasionally in dogs, and hydronephrosis. In both disorders, cell harvest is usually low, with a large amount of fluid. The cellular component of the sample is rarely helpful in identifying further the nature of the cystic structure.

Most inflammatory lesions in the kidney are chronic and produce fibrous connective tissue. Cell harvest from these lesions is usually exceedingly low, and cytology is not typically a useful technique. Pyogenic inflammation can sometimes be diagnosed. Cytology may help diagnose feline infectious peritonitis, although diagnosis using serologic techniques is more common. Because of the usually severe and widespread nature of the inflammation, cell harvest is usually high. The wide mixture of inflammatory cells present in feline infectious peritonitis, with a predominance

of neutrophils, along with an appropriate history, are typical of the disorder.

Mammary Cytology: Cytology is useful to differentiate inflammatory from neoplastic nodular lesions within mammary tissue. Mammary tumors are not commonly inflamed. It is less useful to differentiate the neoplastic conditions.

Neoplastic lesions must be interpreted using the criteria listed above (*see p 1601*). The criteria most useful to determine the behavior and prognosis of a mammary tumor are local tissue and vessel invasion, not cell morphology. These are best assessed histologically rather than cytologically. Therefore, cellular morphology is not necessarily a good guide to tumor behavior. In cats, malignant cells are often uniform and do not exhibit the normal malignant features; the size of the malignant tumor is the most useful prognostic indicator.

CLINICAL HEMATOLOGY

Hematology refers to the study of the numbers and morphology of the cellular elements of the blood—the RBCs (erythrocytes), WBCs (leukocytes), and platelets (thrombocytes)—and the use of these results in the diagnosis and monitoring of disease. (*See also* HEMATOPOIETIC SYSTEM INTRODUCTION, p 4.)

Red Blood Cells: Three RBC measurements are routinely done: packed cell volume (PCV), the proportion of whole blood volume occupied by RBCs; hemoglobin (Hgb) concentration of whole lysed blood; and RBC count, the number of RBCs per unit volume of whole blood. Although these are separate estimations, they are in effect three ways to measure the same thing, and it is incorrect to attempt to interpret them as separate variables. Inasmuch as they do vary in relation to each other, they allow calculation of two further meaningful parameters, mean corpuscular volume (MCV) and mean corpuscular hemoglobin concentration (MCHC).

MCV varies widely between mammalian species, from ~15 fL in goats to ~90 fL in people. Avian and reptilian red cells are even larger, up to 300 fL. Nevertheless,

$$\text{MCV (fL)} = \frac{\text{PCV(Decimal fraction)} \times 1,000}{\text{RBC}(\times 10^{12}/\text{L})}$$

$$\text{MCHC (g/L)} = \frac{\text{whole blood hemoglobin concentration (g/L)}}{\text{PCV(Decimal fraction)}}$$

MCHC varies little with species (or erythrocyte size), at ~ 330 g/L.

Several artifacts can cause significant and potentially misleading alterations to measured RBC parameters: 1) old samples cause RBCs to swell, thus increasing PCV and MCV and decreasing MCHC; 2) lipemia causes a falsely high Hgb reading, and hence a falsely high MCHC; 3) hemolysis causes PCV to decrease while Hgb remains unchanged, again leading to a falsely high MCHC; 4) underfilling of the tube causes RBCs to shrink, causing PCV and MCV to decrease and MCHC to increase; 5) autoagglutination causes a falsely low RBC count, and hence a falsely high MCV.

Visual description of RBC morphology on a Romanowsky stain also provides useful diagnostic information. The most common terms include 1) normocytic—cells are of normal size; 2) macrocytes—abnormally large cells, usually polychromatophilic; 3) microcytes—abnormally small cells, usually caused by a lack of hemoglobin precursors; 4) anisocytosis—variation in size of cells due to macrocytes, microcytes, or both; 5) normochromic—cells are of normal color; 6) polychromasia—variation in color of the cells, which usually describes the appearance of large, juvenile, bluish-staining polychromatophilic macrocytes (these broadly correspond to the “reticulocyte” seen with new methylene blue staining, in which the reticulum represents the remnants of the nucleus); 7) hypochromasia—decrease in staining density of the cells, usually due to a lack of hemoglobin precursors, especially iron; and 8) annulocyte—extreme form of hypochromic cell with only a thin rim of hemoglobin.

PCV is the variable usually used to assess the basic status of the erythron—increased in polycythemia, decreased in anemia—although if a sample is too hemolyzed to allow measurement of PCV, a meaningful Hgb measurement may still be obtained. RBC count as such should not be interpreted clinically.

An abnormally high PCV (polycythemia) may be relative, due to a change in the proportion of circulating RBCs to blood plasma without any change in the size of the erythron, or absolute, due to a real increase in erythron size. Absolute polycythemia may be primary (eg, polycythemia vera or, rarely, erythropoietin-producing tumors) or secondary (a consequence of disease in another organ system). (See also POLYCYTHEMIA, p 43.)

Polycythemia vera and erythropoietin-producing tumors should be suspected only when PCV is very high, normally >0.7 . The

former is characterized by normal, mature RBCs and a normal (or low) erythropoietin concentration, whereas the latter may show a regenerative RBC picture with high erythropoietin concentration. Relative polycythemia may also be associated with very high PCV values, and normal, mature RBCs. Secondary polycythemia generally shows a more modest increase in PCV, often with evidence of regeneration (more so when the cause is pulmonary or cardiac, less so when the cause is hormonal). It is often possible to make the differential diagnosis of polycythemia on clinical grounds.

Abnormally low PCV (anemia) may be caused by loss of blood (hemorrhage), breakdown of RBCs in circulation (hemolysis), or lack of production of RBCs by the bone marrow (hypoplasia or aplasia). Presentation varies according to whether the condition is acute or chronic. Aplastic anemia is always chronic in onset, because anemia occurs gradually as existing cells reach the end of their lifespan. (See also ANEMIA, p 7.)

In acute hemorrhagic anemia, external blood loss is easily appreciated clinically, but blood loss into a body cavity may be determined only on paracentesis. Initially, all hematologic parameters may be normal, because it may take 12 hr for fluid shifts to produce a decrease in the PCV. Within a few days, RBCs become regenerative, with juvenile forms appearing in circulation (except in horses, in which circulating evidence of regeneration is not readily appreciable). These consist of polychromatophilic macrocytes and normoblasts (nucleated RBCs). Late normoblasts have a small, nonviable nucleus and a moderate amount of cytoplasm colored similarly to that of the polychromatophilic macrocytes, whereas early normoblasts have a larger, viable nucleus and scanty cytoplasm. These are most easily distinguished from lymphocytes by their more densely staining nucleus.

If substantial amounts of blood have been lost from the body, the RBC picture may become hypochromic. Thus, this type of anemia shows an increase in MCV and a decrease in MCHC. If bleeding is into a body cavity, hypochromasia may not be evident because hemoglobin precursors will be recycled. However, slight jaundice may be seen as the sequestered cells are broken down. Some sequestered cells may also be returned to the circulation intact, if somewhat misshapen.

In acute hemolytic anemia, PCV will decrease immediately, and in the early stages some jaundice will be evident. In the

very early stages, even a sample collected with extreme care may be markedly hemolyzed. As with hemorrhagic anemia, the RBCs will become regenerative within a few days, with polychromatophilic macrocytes and nucleated RBCs evident. Because hemoglobin precursors are not lost from the body, true hypochromasia is not seen.

Chronic hemorrhagic anemia may be difficult to appreciate if blood is lost in the feces or urine, or due to bloodsucking ectoparasites. Anemia may be severe, and the RBC picture will be regenerative on presentation. Hypochromasia is usually very marked. In very longstanding conditions, depletion of iron and other hemoglobin precursors can become so marked that most of the cells are microcytic, and MCV may paradoxically decrease. Intermittent intra-abdominal hemorrhage leads to a somewhat different picture, because blood shed into the peritoneal cavity can be returned to the circulation. PCV may therefore recover quickly (until the next episode), and signs of depletion of hemoglobin constituents do not emerge.

In chronic hemolytic anemia, RBCs are regenerative on presentation, except that some cases of autoimmune hemolytic anemia (AIHA) paradoxically show little or no regeneration until treatment has been initiated. Hypochromasia is less marked than in hemorrhagic conditions, and misshapen RBCs (including target cells and folded cells) are more common. The spherocyte, in which the erythrocyte loses its classic biconcave shape, is essentially pathognomonic for AIHA. Jaundice may be absent, because the products of the destruction of the RBCs may be cleared by the reticuloendothelial system and the liver as quickly as they are formed.

Hypoplastic and aplastic anemia may be mild if RBC production is merely depressed secondary to some other disease. Protein, mineral, or vitamin deficiencies may cause hypoplastic anemia, but these are more likely to be secondary to another disease (eg, chronic hemorrhage or malabsorption) than simple dietary deficiency. Other diseases may cause depression of erythropoietin production, eg, renal failure, deficiencies of hormones that usually stimulate erythropoietin production (eg, hypothyroidism, hyperadrenocorticism), and chronic, debilitating conditions (eg, chronic infections, chronic parasitism, and neoplasia). RBC morphology is nonregenerative and may be hypochromic if a deficiency state is involved. Paradoxically, vitamin B₁₂ and/or folic acid deficiency

produces a macrocytic RBC picture due to early maturation arrest of the erythrocytes. Neoplasia of the bone marrow may cause severe anemia as erythropoietic elements are crowded out, but some regeneration may be seen as the remaining bone marrow attempts to compensate. In this case, other bone marrow cell lines will also be affected.

True aplastic anemia refers to a failure of the entire bone marrow. The shorter-lived granulocytes and platelets decrease first, followed by a progressively severe anemia that is normocytic and normochromic.

White Blood Cells: The WBCs consist of the granulocytes (neutrophils in most mammals, called heterophils in rabbits, reptiles, and birds [and these look like eosinophils in smears]; eosinophils; and basophils) and the agranulocytes (lymphocytes and monocytes). Although each type is traditionally counted by determination of its percentage of the total WBC population, meaningful interpretation requires that the absolute number of each type be calculated by multiplying the total WBC count by the fraction attributable to the individual cell type. Percentages of each cell type alone are not helpful. An increased percentage that is due to an absolute decrease in another cell type is not an increase at all.

Mature **neutrophils** have a lobulated nucleus, but when demand is high, immature cells with an unlobulated band nucleus (no constriction of the nucleus is more than half the width of the nucleus) may be released into circulation. They function as phagocytes and are important in infectious conditions and in inflammation. Increased neutrophil counts (neutrophilia) are caused by inflammation, bacterial infection, acute stress, steroid effects, and neoplasia of the granulocytic cell line (granulocytic leukemia can be difficult to differentiate from a simple neutrophilia without special stains or bone marrow biopsy). Decreased neutrophil counts (neutropenia) are caused by viral infections, toxin exposure (including foodborne toxins), certain drugs (eg, carbimazole and methimazole), autoimmune destruction of neutrophils, bone marrow neoplasia not involving the granulocytes, and bone marrow aplasia.

Eosinophils are characterized by prominent pink-staining granules on a Romanowsky stain. They inactivate histamine and inhibit edema formation. Increased eosinophil counts (eosinophilia) are caused by allergic/hypersensitivity reactions, parasitism, tissue injury, mast cell tumors, estrus, and pregnancy or

parturition in the bitch. Some large dog breeds (eg, German and Belgian Shepherds, Rottweilers) normally have a relatively high eosinophil count. Extremely high eosinophil counts (hypereosinophilic syndrome), possibly due to an out-of-control hypersensitivity reaction, and eosinophil leukemia (a form of chronic myeloid leukemia) are also described. Decreased eosinophil count (eosinopenia) is almost always caused by the action of glucocorticoids, either endogenous or therapeutic.

Basophils are rare in most species and are characterized by blue-staining granules on a Romanowsky stain. They are more easily seen in cattle. They are closely related to mast cells and, like them, initiate the inflammatory response by releasing histamine. An increased basophil count (basophilia) accompanies eosinophilia in some species as part of the hypersensitivity reaction.

Monocytes are large cells with blue-gray cytoplasm, which may be vacuolated, and a kidney bean-shaped or lobulated nucleus. Their main function is phagocytosis, and they are essentially identical to tissue macrophages. An increased monocyte count (monocytosis) may occur in any chronic disease, especially chronic inflammation, and may be very marked in neoplasia. Monocytes also increase as part of the steroid response in dogs.

Lymphocytes mainly develop outside the bone marrow in the lymph nodes, spleen, and gut-associated lymphoid tissue. They are the smallest of the WBCs, with a round, evenly staining nucleus and sparse cytoplasm. Larger, reactive lymphocytes can be seen after antigenic stimulation, and care must be taken to differentiate them from neoplastic lymphocytes. Their primary function is immunologic, including both antibody production and cell-mediated immune responses. Some survive only a few

days, but many are long-lived. The number in circulation is a balance between populations in the blood, lymph, lymph nodes, and splenic follicles and does not necessarily reflect changes in lymphopoiesis. An increased lymphocyte count (lymphocytosis) may occur for physiologic reasons, especially in cats, but significant increases usually indicate leukemia. Immature or bizarre cells may also be recognized. Decreased lymphocyte counts (lymphopenia) are usually due to an effect of corticosteroids, either endogenous (stress or Cushing disease) or therapeutic, and may also accompany neutropenia in some viral infections, especially the parvoviruses. Lymphopenia may also be a feature of solid-organ lymphosarcomas, when leukemia is absent.

Platelets: Mammalian platelets are pale blue granular fragments (much smaller than RBCs) shed from multinucleate megakaryocytes in the bone marrow; avian and reptilian platelets are true cells with nuclei. They maintain the integrity of the endothelium and act as part of the clotting process to repair damaged endothelium, where they ensure mechanical strength of the clot.

Increased platelet counts (thrombocytosis) occur as a reaction to consumption after injury, when large juvenile platelets may also appear; after splenectomy, as splenic stores are liberated to the circulation; after vincristine treatment, which increases platelet shedding from megakaryocytes; and in megakaryocytic leukemia.

Decreased platelet counts (thrombocytopenia) are caused by autoimmune reactions, thrombotic/thrombocytopenic purpura, bone marrow suppression and aplasia, bone marrow neoplasia, and equine infectious anemia. Signs are petechiation and ecchymosis more than frank hemorrhage, and little may be seen until the platelet count is $<20 \times 10^9/L$. Platelet functional abnormalities present similarly, but platelet numbers and morphology are normal.

Blood Sample Preparation and Evaluation:

In-house hematologic investigations, with a minimum of specialist equipment, can provide almost as much information as a full laboratory analysis, although some estimations are qualitative rather than quantitative.

Blood for hematology should be collected into tubes containing EDTA anticoagulant and immediately mixed well to avoid clotting. Larger (2.5 mL) tubes yield better results than the smaller (1 mL) pediatric

Ecchymotic lesions on the abdomen of a dog.
Courtesy of Ontario Veterinary College.

tubes and are less likely to clot. Nevertheless, it is essential to fill the tube exactly to the mark, so smaller tubes may be unavoidable for small patients. WBC morphology deteriorates most quickly, especially in equine blood, so if the sample cannot be analyzed immediately, a thin blood smear should be submitted to the laboratory with the blood sample.

PCV is measured by microhematocrit, which is the reference method. A capillary tube is filled $\frac{3}{4}$ full with well-mixed blood and sealed at one end; heat-sealing is best if a Bunsen burner is available, otherwise a proprietary clay pad is used. The tube is spun in a high-speed microhematocrit centrifuge for 6 min, and the PCV is read using a microhematocrit reader with a sliding cursor. The appearance of the plasma (eg, normal, icteric, hemolyzed, lipemic) and the thickness of the buffy coat, which gives a very rough guide to total WBC count, should be noted.

Further information is obtained from a blood film. This is made by using one slide, with a corner broken off as a spreader, to pull a small drop of blood across a clean slide into a thin film. A suitable film is thin (one erythrocyte thick) and tapers to a feathered edge before the far end of the slide. The broken corner of the spreader slide ensures two straight edges parallel to the long edges of the slide. Immediately after the film is spread, it is dried quickly by fanning the slide in the air. Airdried smears can be sent to the laboratory in a slide mailer or stained and examined in the practice. Commercial rapid Romanowsky-type stains merely require the slide to be dipped in three colored solutions in succession. Cell morphology is clear and comparable to more permanent stains such as Leishman or May-Gruenwald-Giemsa, although quality deteriorates after a few days. The slide should be allowed to dry naturally or dried with a hair dryer (not wiped dry), and examined under oil immersion.

Clinically useful information may be easily achieved in-house for all hematologic variables. The main deficiency is the absence of a numerical WBC count, and hence of numerical values for the differential WBC count. This may be acceptable for an interim emergency investigation, and a WBC count using a hemocytometer slide may be attempted. A mirrored slide with an Improved Neubauer ruling may be used, with a cover slip fitted so that Newton rings are visible on both sides. The blood sample is diluted 1:20 with Turck fluid or a similar

diluent. An automatic pipette capable of dispensing 0.95 mL and 0.05 mL (50 μ L) should be used to ensure an accurate dilution. The sample should be mixed well and allowed to stand for 10 min while the stain is taken up by the cells. The chamber of the hemocytometer is then filled by using a capillary (PCV) tube. The number of cells in each of the four large corner squares of the grid are counted, and the total divided by 20 to calculate the total WBC count $\times 10^9/L$.

Several hematologic instruments are available for in-practice use. Those based on centrifugation, in which WBC measurements are made by spreading a stained buffy coat, are not true hematology analyzers, but give approximate counts. Although a numerical estimate of total WBC count is provided, the differential WBC count cannot distinguish between lymphocytes and monocytes, and results do not always correlate well with standard methods. This method is appropriate only as an emergency approximation, and a blood film must always be examined in addition. It is also wise to check the PCV by microhematocrit.

Impedance counters (Coulter principle) are used by diagnostic laboratories and perform well in experienced hands. However, it is difficult to achieve optimal performance without trained technical staff. Instruments not based on the Coulter principle should be avoided for veterinary use, because their results do not necessarily compare well on nonhuman samples. Instruments providing automated differential counts perform poorly on nonhuman blood, and results must never be accepted without also checking a blood film. No hematology laboratory should be without the facility for examining blood films, and a blood film should be examined for every patient sample. Quality assurance issues are the same as those for biochemistry laboratories (*see p 1590*). If accuracy and reliability cannot be guaranteed to the same standard as the referral laboratory, then results should not be relied on without external confirmation.

Red Blood Cells: The size, uniformity of size, and presence of microcytes, macrocytes, and abnormally shaped cells should be noted, along with cell color, uniformity of color, and the presence of hypochromasia, polychromasia, and nucleated RBCs. An overall descriptive assessment of the RBC picture should be made, including the degree of regeneration or hypochromasia, if any.

White Blood Cells: A qualitative estimate of numbers should be made (ie, very low, low, normal, high, very high). This can be remarkably consistent with practice. The proportions of each cell type can be estimated, or preferably, a formal differential count of 100–200 cells performed. Unusual or abnormal WBC forms (eg, band or toxic neutrophils), or pathologic cells (eg, polymorphocytes, lymphoblasts, or mast cells) should be noted.

Platelets: A qualitative estimate of platelet numbers, based on how many can be seen in a typical high-power field (oil immersion) should be made. Several fields should be examined, more if numbers appear low. Results can be ranked as none seen (on entire slide), rare (very few on entire slide), low in number (<5 per high-power field), adequate (5–20 per high-power field), or abundant (>20 per high-power field). Normal platelet numbers in the horse are about half those of other species. In a sample more than a few hours old, platelets may clump into rafts, leaving areas of the slide apparently devoid of platelets. Slides should be scanned for rafts before reporting platelet numbers as low. Enlarged or macroplatelets should also be noted.

URINALYSIS

Urinalysis is an important laboratory test that can be readily performed in veterinary practice and is considered part of a minimum database. It is useful to document various types of urinary tract diseases and may provide information about other systemic diseases, such as liver failure and hemolysis. Urine may be collected by cystocentesis, urethral catheterization, or voiding. Urine should be evaluated within 30 min, but if this is not possible, it may be refrigerated for up to 24 hr or submitted to an outside diagnostic laboratory; however, this may result in crystal precipitation. Refrigeration does not alter urine pH or specific gravity. If cytologic evaluation is required and a delay in preparing the slides is anticipated, then a preservative should be added. A few drops of 10% formalin (exact concentration not necessary) is better than boric acid. However, the usual Romanowsky stains are unsuitable with formalin; if submitting to an outside laboratory, it should be communicated that formalin has been added.

Urine Appearance

Color: Normal urine is typically transparent and yellow or amber on visual inspection. The intensity of color is in part related

to the volume of urine collected and concentration of urine produced; therefore, it should be interpreted in context of urine specific gravity. Significant disease may exist when urine color is normal. Abnormal urine color may be caused by presence of endogenous or exogenous pigments, but it does not provide specific information. Interpretation of semiquantitative reagent strips, which are colorimetric tests, requires knowledge of urine color because discolored urine may result in a false-positive result. Equine urine may turn brown after a period of time.

Clarity: Urine is typically clear but may become less transparent with pigmenturia, crystalluria, hematuria, pyuria, lipiduria, or when other compounds such as mucus are present. Depending on the cause, increased turbidity may disappear with centrifugation of the sample.

Odor: Normal urine has a slight odor of anuria; however, the odor depends on urine concentration. Some species, such as cats and goats, have pungent urine odor because of urine composition. Bacterial infection may result in a strong odor due to pyuria; a strong ammonia odor may occur if the bacteria produce urease.

Urine Chemistries

Urine must be at room temperature for accurate measurement of urine specific gravity and for chemical analysis. These tests are usually done before centrifugation; however, if urine is discolored or turbid, it may be beneficial to perform these tests on supernatant (*see p 1617*).

Specific Gravity: Specific gravity is defined as the ratio of the weight of a volume of liquid to the weight of an equal volume of distilled water; therefore, it depends on the number, size, and weight of particles in the liquid. It is different from osmolality, which depends only on the number of particles in the liquid; measurement of osmolality requires specialized instrumentation.

The urine specific gravity (SG) is determined using a refractometer designed for veterinary samples, which includes a scale calibrated specifically for cat urine. SG for species other than cats should be determined using the scale for dogs. In healthy animals, SG is highly variable, depending on fluid and electrolyte balance of the body. It is normally at least 1.015. Interpretation of SG, therefore, depends

on the clinical presentation and serum chemistry findings. (See also URINARY SYSTEM INTRODUCTION, p 1494.) An animal that is dehydrated or has other causes of prerenal azotemia will have hypersthenuric urine with an SG >1.025 – 1.040 (depending on species). Dilute urine in a dehydrated or azotemic animal is abnormal and could be caused by renal failure, hypo- or hyperadrenocorticism, hypercalcemia, diabetes mellitus, hyperthyroidism, and diuretic therapy. In cases of diabetes insipidus, values <1.010 can be expected. Glucosuria increases the SG despite increased urine volume.

Semiquantitative, Colorimetric

Reagent Strips: Reagent strips such as Multistix® or Chemstrip® can be used to perform several semiquantitative chemical evaluations simultaneously. They are used routinely to determine urine pH, protein, glucose, ketones, bilirubin/urobilinogen, and occult blood. Some reagent strips include test pads for leukocyte esterase (for detection of WBCs), nitrite (for detection of bacteria), and SG; these are not valid in animals and should not be used. Reagent strips are adversely affected by moisture and have a limited shelf life. Bottles should be kept tightly capped, and unused strips should be discarded after their expiration date.

Urine pH: Urine pH is typically acidic in dogs and cats and alkaline in horses and ruminants, but varies depending on diet, medications, or presence of disease. Reagent strip colorimetric test pads for pH determination are accurate to within ~ 0.5 pH units. For example, a reading of 6.5 means the actual pH is likely to be between 6.0 and 7.0. Portable pH meters are more accurate than pH colorimetric test pads. A bacterial urinary tract infection with a urease-producing microbe will result in alkaluria. Urine pH will affect crystalluria because some crystals, such as struvite, form in alkaline urine, whereas other crystals, such as cystine, form in acidic urine.

Protein: The protein test pad uses a color indicator (tetrabromophenol blue), which detects primarily albumin in urine. Results range from 10 mg/dL to 1,000 mg/dL. Proteinuria can occur from prerenal (fever, strenuous exercise, seizures, extreme environmental temperature, and hyperproteinemia), renal (primarily glomerular and occasionally tubular disease), or postrenal (inflammation, hemorrhage, and infection) causes. A positive reaction must be interpreted in light of SG, pH, and urine

sediment examination. For example, a trace amount of protein in concentrated urine is less significant than a trace amount of protein in dilute urine. Alkaluria will give a false-positive reaction. Likewise, presence of other proteins, such as Bence-Jones proteins, will give false-negative results. Proteinuria can be measured using sulfosalicylic acid precipitation, which detects albumin and globulins; however, it is not accurate in dogs and cats. If proteinuria is present with an inactive urine sediment, its significance can be verified and quantitated by dividing the urine protein concentration by the urine creatinine concentration (urine protein to urine creatinine ratio [UP:UC]). Interpretation of a UP:UC is as follows: $<0.5:1$ (dogs) and $<0.4:1$ (cats) is normal, 0.4 or 0.5 – $1:1$ is questionable, and $>1:1$ is abnormal. With primary renal azotemia, a UP:UC $>0.5:1$ in dogs and $>0.4:1$ in cats is considered abnormal. A semiquantitative microalbuminuria test is available to detect urinary albumin in the range of 1–30 mg/dL. It uses ELISA technology specific for canine or feline albumin. Because of minor species differences in albumin, there are different kits for dogs and cats. The microalbuminuria test detects lower concentrations of albumin than a standard dipstick test pad. Hematuria must be macroscopic to increase the microalbuminuria or UP:UC; however, pyuria increases both.

Glucose: Glucose is detected by a glucose oxidase enzymatic reaction that is specific for glucose. Glucosuria is not present normally because the renal threshold for glucose is >180 mg/dL in most species and >240 mg/dL in cats. With euglycemia, the amount of filtered glucose is less than the renal threshold, and all of the filtered glucose is reabsorbed in the proximal renal tubules. Glucosuria can result from hyperglycemia (due to diabetes mellitus, excessive endogenous or exogenous glucocorticoids, hepatocutaneous syndrome, or stress) or from a proximal renal tubular defect (such as primary renal glucosuria or Fanconi syndrome). If glucosuria is present, blood glucose concentration should be determined. False-negative results can occur with high urinary concentrations of ascorbic acid (vitamin C) or with formaldehyde (a metabolite of the urinary antiseptic, methenamine, which may be used for prevention of bacterial urinary tract infections). False-positive results may occur if the sample is contaminated with hydrogen peroxide, chlorine, or hypochlorite (bleach).

Ketones: Ketones are produced from fatty acid metabolism and include acetoacetic acid, acetone, and β -hydroxybutyrate. The ketone test pad detects acetone and acetoacetic acid, but not β -hydroxybutyrate (which can be measured in blood and urine using a point-of-care instrument or a biochemistry analyzer). The test pad contains nitroprusside that reacts with acetoacetic acid and acetone to cause a purple color change; it is more sensitive to acetoacetic acid than acetone. Ketonuria is associated with primary ketosis (ruminants), ketosis secondary to diabetes mellitus (small animals), consumption of low-carbohydrate diets (especially in cats), and occasionally with prolonged fasting or starvation. A false-positive reaction can occur with presence of reducing substances in urine.

Bilirubin/Urobilinogen: When hemoglobin is degraded, the heme portion is converted to bilirubin, which is conjugated in the liver and excreted in bile. Some conjugated bilirubin is filtered by the glomerulus and excreted in urine. In dogs, but not cats, the kidney can metabolize hemoglobin to bilirubin and secrete it. Male dogs have a higher secretory ability than females. Dipstick reagent pads use diazonium salts to create a color change and are more sensitive to conjugated bilirubin than unconjugated bilirubin. Bilirubinuria occurs when conjugated bilirubin exceeds the renal threshold as with liver disease or hemolysis. In dogs with concentrated urine, a small amount of bilirubin can be normal. Pigmenturia and phenothiazine may result in a false-positive reaction; false-negative reactions may occur with large amounts of urinary ascorbic acid (vitamin C).

Urobilinogen, formed from bilirubin by intestinal microflora, is absorbed into the portal circulation and excreted renally. A small amount of urinary urobilinogen is normal. Increased urinary urobilinogen occurs with hyperbilirubinemia; a negative test may be seen with biliary obstruction. However, the test is not specific enough to be clinically useful.

Occult Blood: The occult blood test pad uses a "pseudoperoxidase" method to detect intact RBCs, hemoglobin, and myoglobin. A positive reaction can be due to hemorrhage (hematuria), intravascular hemolysis (hemoglobinuria), or myoglobinuria. The latter two processes can be distinguished by examination of plasma: plasma will appear pink to red after intravascular hemolysis, whereas myoglo-

bin is rapidly cleared from plasma, resulting in clear plasma. As with other colorimetric test pads, discolored urine may yield false-positive results. A positive result should be interpreted with microscopic examination of urine sediment.

Urine Sediment

Microscopic examination of urine sediment should be part of a routine urinalysis. For centrifugation, 3–5 mL of urine is transferred to a conical centrifuge tube. Urine is centrifuged at 1,000–1,500 rpm for ~3–5 min. The supernatant is decanted, leaving ~0.5 mL of urine and sediment in the tip of the conical tube. The sediment is resuspended by tapping the tip of the conical tube against the table several times. A few drops of the sediment are transferred to a glass slide, and a cover slip is applied. Examination of unstained urine is recommended for routine samples. Microscopic examination is performed at 100 $\times$ (for crystals, casts, and cells) and 400 $\times$ (for cells and bacteria) magnifications. Contrast of the sample is enhanced by closing the iris diaphragm and lowering the condenser of the microscope. Stains such as Sedistain[®] and new methylene blue can be used to aid in cell identification but may dilute the specimen and introduce artifacts such as stain precipitate and crystals. Use of a modified Wright stain increases the sensitivity, specificity, and positive and negative predictive values for detection of bacteria. For some tests, air dried, stained smears are necessary.

Red Blood Cells: In an unstained preparation, RBCs are small and round and have a slight orange tint and a smooth appearance. Normal urine should contain <5 RBCs/field at 400 $\times$ magnification. Increased RBCs in urine (hematuria) indicates hemorrhage somewhere in the urogenital system; however, sample collection by cystocentesis or catheterization may induce hemorrhage.

White Blood Cells: WBCs are slightly larger than RBCs and have grainy cytoplasm. Normal urine should contain <5 WBCs/field at 400 $\times$ magnification. Increased WBCs (pyuria) can occur due to inflammation, infection, trauma, or neoplasia. Catheterization or collection of voided urine may introduce a few WBCs from the urogenital tract.

Epithelial Cells: Transitional epithelial cells, a common urine contaminant derived

from the bladder and proximal urethra, resemble WBCs but are larger. They have a greater amount of grainy cytoplasm and a round, centrally located nucleus. In a voided urine sample, squamous epithelial cells may be seen. They are large, oval to cuboidal in shape, and may or may not contain a nucleus. Occasionally, neoplastic transitional cells may be seen in an animal with a transitional cell carcinoma. Neoplastic squamous cells may be seen in an animal with a squamous cell carcinoma.

Cylindruria (Casts): Casts are elongated, cylindrical structures formed by mucoprotein congealing within renal tubules and may contain cells. Hyaline casts are pure protein precipitates; they are transparent, have parallel sides and rounded ends, and are composed of mucoprotein. They may occur with fever, exercise, and renal disease. Epithelial cellular casts form from entrapment of sloughed tubular epithelial cells in the mucoprotein; they may be seen with renal tubular disease. Granular casts are thought to represent degenerated epithelial cellular casts. Waxy casts have a granular appearance and are thought to arise from degeneration of longstanding granular casts. They typically have sharp borders with broken ends. Other cellular casts include RBC casts and WBC casts and are always abnormal. RBC casts form because of renal hemorrhage. WBC casts form because of renal inflammation, as with pyelonephritis. Fatty casts are not common but can be seen with disorders of lipid metabolism, such as diabetes mellitus. A few hyaline or granular casts are considered normal. However, presence of cellular casts or other casts in high numbers indicates renal damage, and may be one of the earliest laboratory abnormalities noted with toxic damage to renal epithelial cells (eg, gentamicin, amphotericin B).

Infectious Organisms: The presence of bacteria in urine collected by cystocentesis indicates infection. Small numbers of bacteria from the lower urogenital tract may contaminate voided samples or samples collected by catheterization and do not indicate infection. Bacterial rods are most easily identified in urine sediment. Particles of debris may be mistaken for bacteria. Suspected bacteria can be confirmed by staining urine sediment with Gram stain; however, aerobic culture is best to confirm a bacterial urinary tract infection. Rarely, yeast and fungal hyphae and parasitic ova may be seen in urine sediment. Their presence is not always associated with

clinical disease. Parasitic ova observed include those of *Stephanurus dentatus*, *Capillaria plicata*, *C. felis*, and *Diocotophyma renale*. Additionally, microfilariae of *Dirofilaria immitis* may be seen in urine sediment.

Crystals: Many urine sediments contain crystals. The type of crystal present depends on urine pH, concentration of crystallogenic materials, urine temperature, and length of time between urine collection and examination. Crystalluria is not synonymous with urolithiasis and is not necessarily pathologic. Furthermore, uroliths may form without observed crystalluria. Many urine samples are examined at room temperature, which may alter the number of crystals present, and the result may not represent the situation *in vivo*.

Struvite crystals are commonly seen in canine and feline urine. Struvite crystalluria in dogs is not a problem unless there is a concurrent bacterial urinary tract infection with a urease-producing microbe. Without an infection, struvite crystals in dogs are not associated with struvite urolith formation. However, some animals (eg, cats) do form struvite uroliths without a bacterial urinary tract infection. In these animals, struvite crystalluria may be pathologic. Struvite crystals appear typically as “coffin-lids” or “prisms”; however, they may be amorphous.

Calcium oxalate crystalluria occurs less commonly in dogs and cats. If persistent, it may indicate an increased risk of calcium oxalate urolith formation, which has been increasing in some countries throughout the past few years. (See also UROLITHIASIS, p 1502, and p 1525.) However, calcium oxalate and calcium carbonate crystalluria is common in healthy horses and cattle. Calcium oxalate dihydrate crystals appear as squares with an “X” in the middle, or “envelope-shaped.” Calcium oxalate monohydrate crystals are “dumb-bell” shaped. An unusual form of calcium oxalate crystals is typically seen in association with ethylene glycol toxicity (see p 3046). These crystals are found in neutral to acidic urine. They are small, flat, and colorless and are shaped like “picket fence posts.”

Ammonium acid urate crystals suggest liver disease (eg, portosystemic shunt). These crystals occur in acidic urine and are yellow-brown spheres with irregular, spiny projections; however, they may also be amorphous. Certain species, such as birds and reptiles, and certain breeds of dogs, specifically Dalmatians, can normally have ammonium acid urate crystalluria.

Cystine crystals are six-sided and of variable size. They are seen in acidic urine. Presence of cystine crystals represents a proximal tubular defect in amino acid reabsorption. Cystinuria has been reported in many breeds of dogs and rarely in cats. Dachshunds, Newfoundland, English Bulldogs, and Scottish Terriers have a high incidence of cystine urolithiasis.

Bilirubin crystals occur with bilirubinuria; however, they may be normal in small numbers in dogs.

Lipids: Fat droplets are commonly present in urine from dogs and cats and may be mistaken for RBCs. They often vary in size and tend to float on a different plane of focus than the remainder of the sediment. They are not considered to be pathologic.

Spermatozoa: Spermatozoa may be seen normally in urine collected from reproductively intact male dogs.

Plant Material: Occasionally, plant material may be seen in urine samples collected by voiding. When present, they indicate contamination of the urine sample and are not pathologic.

Bladder Tumor Antigen Test

The bladder tumor antigen test can be used to screen for transitional cell carcinoma in dogs. The results are not specific for transitional cell carcinoma, and non-neoplastic disease (eg, urinary tract infections, hematuria, etc) can give positive results. A negative test, however, is meaningful in that a transitional cell carcinoma is not likely to be present. This test may be useful for routine screening of dogs at higher risk of developing transitional cell carcinoma (eg, Scottish terriers) that do not have other signs or laboratory findings of lower urinary tract disease. This tests for the presence of basement membrane fragments and is a color reaction using a commercial test kit.

PARASITOLOGY

Internal Parasite (Endoparasite)

Diagnosis in Small Animals: Diagnosis of internal parasites in small animals is typically performed by examination of feces for parasite eggs. Fecal samples should be fresh, preferably collected from the animal during the act of defecation or from the rectum using a fecal loop during the physical examination. Specimens should be submitted to a diagnostic laboratory in a sealed container, labeled with proper

identification. Specimens should be fixed in 10% formaldehyde solution or sent chilled. Other preservative solutions (eg, sodium acetate formalin, polyvinyl alcohol, available in commercial mailer kits) better preserve protozoa and facilitate special staining (eg, trichrome, iron hematoxylin).

Routine examinations should be done by both direct fecal smear and fecal flotation. Direct smears are prepared by mixing feces (an amount of feces fitting on one-half the tip of a wooden applicator stick) with 1 drop each of saline (for motile organisms) and Lugol's iodine stain (to see internal morphologic structures, eg, those of *Giardia*), and covering with separate coverslips on the same slide. Flotation methods concentrate diagnostic stages and provide a cleaner final preparation, using ~2 g of feces. Sugar (specific gravity [SG] 1.27) and sodium nitrate (SG 1.39) are commonly used flotation media. Zinc sulfate flotation (SG 1.18), repeated on 3 consecutive days, is the method of choice to reveal *Giardia* cysts, which are intermittently shed in feces. Motile nematode larvae may be collected and concentrated by Baermann sedimentation; a convenient method is to place ~2 g of feces on several sheets of cotton gauze in a tea strainer suspended in the wide end of a large, conical funnel fitted with a rubber tube and stopcock. The funnel is filled with warm tap water or saline for 1 hr before sediment examination. Larvae descend within the funnel due to gravity and are collected from the end of the stopcock for microscopic examination. Special procedures, such as formalin-ethyl acetate sedimentation, may be used for parasitic larval stages that do not float well.

Sheather's sugar (SG 1.30) can be used to detect small oocysts of *Cryptosporidium* (4–6 μ) or *Toxoplasma* (12 μ) by focusing "just under the coverslip. Oocysts "float up" to the under-surface of a coverslip placed on the slide for 10 min before examination.

A direct smear using 1 drop of blood can be used to detect motile microfilariae of *Dirofilaria immitis*, but this should not be the sole means of detection. More accurate examination of blood may be done by a modified Knott's test: 1 mL blood is added to 9 mL of 2% formalin solution in a 15-mL tube and centrifuged at 1,500 rpm. The supernatant is discarded and a drop of methylene blue stain is mixed with the sediment "button," which is pipetted onto a microscope slide, covered with a coverslip, and examined to differentiate microfilariae of *D immitis* from those of the nonpathogenic *Dipetalonema reconditum*. Commercial filtration and staining procedures are

effective alternatives to the modified Knotts' test. Animals on heartworm preventive become amicrofilaremic, and an occult heartworm test using a commercially available ELISA for circulating uterine antigen of adult female *Dirofilaria* is the method of choice for treated dogs. Feline dirofilariasis cannot be reliably diagnosed by microfilaremia or antigenemia tests, because heartworm numbers are typically too low; antibody titers to *D. immitis* are used to detect prior exposure and possible current infection in cats.

Internal Parasite (Endoparasite)

Diagnosis in Livestock: Fresh fecal samples from livestock should be collected from pasture or, preferably, per rectum using plastic gloves. Samples should be placed in a properly identified, sealed specimen jar. A representative number of herd samples should be collected from a minimum of 10 animals to account for the typical high individual variation in numbers of eggs shed. Samples can be combined after thorough mixing to enable examination of a single herd composite sample.

Quantitative fecal egg counts by the modified Wisconsin centrifugal flotation procedure or similar methods can be used to estimate relative infection burden for nematodes of the "GI parasite complex" (eg, trichostrongylid larvae of cattle), while also detecting coccidia and other parasites such as lungworm larvae and tapeworms. Three grams of feces are placed in a container, suspended in ~15 mL water, strained through a gauze square into a 15-mL tube, and centrifuged (1,500 rpm for 3 min). The supernatant is decanted and the sediment mixed with saturated sugar solution, filling the tube enough to form a positive meniscus before placing a 22 × 22 mm coverslip on the lip of the test tube. The tube is centrifuged again at low speed (1,500 rpm for 5 min). The coverslip, with the surface film containing eggs, is removed and transferred to a microscope slide for counting of trichostrongylid eggs in cattle feces or strongylid eggs in horse feces. The total is divided by 3 to derive eggs/g (EPG). Other parasites are noted, if present, with a general abundance designation of +1 (few), +2 (small number), +3 (large number), or +4 (too numerous to count).

A saturated solution of table salt (SG 1.20) is an inexpensive alternative medium for diagnosis of livestock parasites, although salt may be highly corrosive to metal surfaces. Magnesium sulfate (SG 1.20) is the preferred medium for swine

feces. Special slides containing chambers with etched areas of known volume are also used to estimate EPG, especially for small ruminants. Feces in a strained solution (usually saturated salt) are introduced into each chamber with a Pasteur pipette, and the eggs are counted under low-power magnification. A commonly used counting slide is the McMaster slide, which has two chambers, each with a volume of 0.15 mL under the etched area. For example, if 3 g of feces are mixed with 42 mL of concentrate solution, then each egg counted is multiplied by 50 to yield the number of EPG in the fecal sample. Acceptable correlation between the EPG and the relative worm burden is often possible in young animals, although low (<5 EPG) or negative counts are typically found in adult animals. In young cattle, which generally have EPG counts 10 times that of adult animals, EPG counts >50 reflect a moderate infection, and EPG counts >500 indicate a heavy burden and a need for treatment.

Because fluke eggs do not float readily, quantitative fecal sedimentation procedures are usually used. Two grams of feces are mixed with 35 mL soapy solution (2% liquid detergent) and strained through gauze into a 50-mL centrifuge tube. The tube is filled with soapy water and allowed to stand for 3 min, after which ½ of the supernatant is discarded. This is repeated 2–3 times until the supernatant is clean. All but 15 mL is poured off, 2 drops of new methylene blue are added, and the eggs counted with a dissecting microscope in a gridded Petri dish or by examining several coverslipped microscope slides. The eggs of the liver fluke, *Fasciola hepatica*, can be differentiated from those of *Paramphistomum* spp, the rumen fluke, by the golden color, more barreled shape, and slightly larger size of eggs of *F. hepatica* versus the gray color, more pointed end, and smaller size of the usually nonpathogenic rumen fluke. Commercial sieve-sediment kits can reduce sample preparation time by 50%. In cattle, *Fasciola* EPG counts >3 suggest economic losses; EPG >10 may be associated with clinical signs.

External Parasite (Ectoparasite) Examination in Small Animals and Livestock:

Animals with dermatoses should be evaluated by examining for ectoparasites or evidence of their presence. For example, fleas may not be seen on a cat or dog, but small black flecks of flea excrement (flea frass or flea "dirt") that produce a reddish stain when placed on a moistened paper towel may be noted. Skin

must sometimes be scraped to diagnose parasites. A scalpel blade is used for the deep scrapings (until blood oozes) needed to demonstrate parasites that live in burrows (eg, *Sarcoptes*) or hair follicles (*Demodex* spp). The scraped material is placed in a drop of mineral oil on a slide, and the entire area under the coverslip is scanned under low-power magnification. A few drops of 10% potassium hydroxide solution may be added to clear debris and allow better visualization.

SEROLOGIC TEST KITS

In-house serologic test kits continue to improve in reliability, ease of use, and types available. They include tests for infectious disease by measuring either antigens or antibodies. Antibody levels can also be measured to establish the presence of adequate protection to an infectious agent. However, these levels are not an absolute measure of protection. High serum antibody levels do not always confer protection, and low levels do not always indicate susceptibility to infection. The level of cell-mediated immunity is also important. Measurement of hormone levels also use serologic tests. Many of these tests are ELISA that may be microwell or membrane-based, but other types, including immunomigration, immunochromatography, and agglutination tests, are also available. Sample requirements may be plasma, serum, whole blood, feces, or saliva, depending on the test format.

Feline Leukemia Virus (FeLV):

Serologic testing for FeLV is important to identify infected cats and prevent transmission of the virus (see p 790). Testing is also recommended before vaccination against FeLV, because vaccination of infected cats will not limit development or transmission of disease. Most currently available in-house diagnostic kits are designed to detect soluble FeLV-specific *gag* protein p 27, which is produced in large amounts during viremia. The time between infection and the presence of detectable antigen varies but is likely to be within 28–30 days. Vaccination against FeLV will not yield a positive test result when antigen tests are used, nor will the presence of maternally derived antibodies in kittens. Testing serum, plasma, or whole blood is considered more reliable than testing saliva or tears. Most test kits have positive and negative controls incorporated into the kit, so technical problems with running the test may be detected.

A negative result on a screening test is very reliable; however, false-positive results may occur with the tests of soluble antigen, especially in a population of cats with a low incidence of disease. A true positive result may reflect either transient or persistent viremia, so clinical decisions should not be based on a single test result. Confirmation of positive results, especially in asymptomatic cats, should be pursued by additional testing such as soluble antigen testing using a kit from a different manufacturer or immunofluorescent antigen testing on blood or bone marrow. Cats with discordant results should be retested using both test methods in 60 days and should probably be considered potentially infective until their status is clarified.

Some cats previously thought to have cleared infection have been identified using real-time PCR, which is a very sensitive method to detect cell-associated FeLV proviral DNA or viral RNA. These cats are proviral DNA positive but FeLV antigen negative and are unlikely to shed virus or develop clinical disease. However, proviral FeLV could be transmitted in blood transfusions, so potential feline blood donors should be PCR negative for FeLV.

Feline Immunodeficiency Virus (FIV):

Because the concentration of FIV antigen in the blood of infected cats is often very low, in-house diagnostic tests are designed to detect anti-FIV antibodies rather than antigen. Test kits yield a positive or negative result for antibody rather than a titer. Antibodies usually develop within 60 days of infection, but this period is quite variable, and a few infected cats do not develop detectable antibody levels. Once present, antibodies appear to be present for >2 yr, except for those transiently detectable in kittens that have maternally derived antibodies. A kitten <6 mo of age that tests positive should be retested after 6 mo of age for this reason. If the test is still positive, the kitten is most likely infected.

With the currently available ELISA in-house test kits, sensitivity is high. However, these tests cannot distinguish between antibodies produced in response to vaccination with FIV vaccine and those produced by natural infection. An ELISA test that appears to successfully discriminate between antibodies produced in response to vaccination and those produced in natural infections has been developed but is not available for commercial use. A reasonable approach is to use the in-house test as a screening test. A negative result is a fairly reliable indicator that the cat is not

infected. Positive results, especially in asymptomatic cats, should be confirmed by another test such as Western blot if available. Kittens born to vaccinated queens are antibody-positive for a variable length of time.

Canine Parvovirus (CPV): Both ELISA and immunomigration test kits are available for detection of CPV antigen in feces. These tests are fairly specific for the virus, but dogs that have been recently vaccinated may transiently shed antigens detected by the test kits. The sensitivity is somewhat lower for several reasons. Fecal shedding occurs for only ~7–10 days, beginning on day 3–5 after exposure, so virus is not always detectable in dogs with clinical signs. Blood in the feces as well as the formation of antigen-antibody complexes, with antibodies from the blood or exudate present in the gut, may be associated with false-negative results. It appears that in-house test kits may have decreased sensitivity to the new CPV2c strain.

Although in-house test kits for diagnosis of CPV are not licensed for use in cats, several studies have shown they can be used to detect feline panleukopenia virus in cat feces. The specificity and sensitivity are not known. Some cats test positive after vaccination, even when inactivated virus vaccines are used.

In-house tests for assay of anti-CPV antibodies have become available to evaluate the need for revaccination and the presence of possibly interfering maternal antibodies. These tests are not intended to diagnose parvovirus infection and do not distinguish between natural exposure and vaccine-induced antibodies. Currently available test kits include ELISA and immunochromatographic tests. They are semiquantitative and use color changes in positive control wells compared with color changes in samples to determine relative antibody levels. The level of anti-CPV antibody protective against infection is not known, but results are interpreted based on protective titers measured by other methods. PCR is widely available for detection of virus in feces.

Canine Distemper Virus (CDV):

In-house test kits for determination of antibodies to CDV are available, usually in combination with canine parvovirus antibody testing. These tests are semiquantitative ELISA for anti-canine distemper IgG in serum or plasma. They may be used to evaluate the need for revaccination and to determine the level of maternal antibody

present in puppies. They are less useful for diagnosis of infection with CDV. An immunochromatography-based assay for CDV antigen has been developed and has good sensitivity and specificity, especially when conjunctival swabs are the sample used; sensitivity and specificity are somewhat less for blood and nasal swabs. This assay is not currently available as an in-house test kit.

***Borrelia burgdorferi*:** Lyme disease (see p 659) is caused by the tickborne spirochete *B burgdorferi*. In general, diagnostic tests for this infection have had several potential problems, including relatively high levels of positive results in clinically healthy animals, persistence of antibodies after apparent resolution of clinical disease, interpretation of antibody titers in vaccinated dogs, and the fact that detectable antibody may not be present until 4–6 wk after exposure. An in-clinic ELISA test kit for detection of anti-*B burgdorferi* antibodies in serum or plasma minimizes some of these problems by using a synthetic peptide (C_6) based on a conserved *B burgdorferi*-specific protein. This protein is important in inducing a humoral immune response by 3–5 wk after natural infection in dogs. Vaccination does not induce a cross-reactive immune response to this antigen, so assays using the C_6 protein are able to distinguish vaccine-induced antibodies from those produced in response to natural infections. C_6 -based assays are also more specific than previous tests, because there is no cross-reactivity with other tickborne agents or with autoimmune antibodies.

A currently available in-house test assay for anti-*B burgdorferi* antibodies is a screening test that gives only a positive or negative result and is thus not quantitative. Although licensed for dogs, this test kit also has been validated in cats and horses. Quantitative assays, performed in reference laboratories, can be used to monitor treatment efficacy (ie, detection of decreasing antibody titers), but these results are not always conclusive.

***Ehrlichia canis*:** Canine ehrlichiosis (see p 803) is a tickborne disease caused by one of several species of *Ehrlichia*. It can be associated with thrombocytopenia, anemia, and neutropenia as well as other nonspecific clinical signs. Although identification of *Ehrlichia* morulae in leukocytes can be diagnostic for this infection, serologic assay for detection of antibodies is more common and has better sensitivity. In-house tests for

ehrlichiosis are either qualitative (giving only a positive or negative result) or semiquantitative tests for antibodies to *E. canis*. Those currently available are ELISA to be performed on serum, plasma, or whole blood. The test kits use either recombinant analogues of major outer membrane proteins of *E. canis* or whole *E. canis* proteins as the antigen. The different *Ehrlichia* species stimulate antibodies that appear to cross-react in these assays, for the most part. Because anti-*E. canis* antibodies may be very long-lived and may be present in subclinical infections, detection of these antibodies does not distinguish between exposure and *Ehrlichia*-induced illness and cannot reliably indicate success of response to therapy.

Brucella canis: *B. canis* is not a problem in some countries, and tests are not always readily available. However, infection may be subclinical, or it may cause a variety of clinical signs, including abortion, infertility, and discospondylitis (see p 1402). Infection most often occurs during mating; thus, testing of breeding animals is important in disease prevention. A rapid slide agglutination test that includes a 2-mercaptoethanol (2-ME) step to reduce false-positive results by eliminating nonspecific IgM reactions is available as an in-house diagnostic kit. This assay detects serum antibody to surface antigens of the bacteria. Reports of sensitivity and specificity of this test vary depending on the confirmatory test used. ELISA and immunochromatographic assays have been developed for qualitative and semiquantitative tests for anti-*B. canis* antibodies. Positive results obtained using any of these test kits should be confirmed with PCR or blood culture.

Heartworm Antigen—Dogs: Serologic testing for heartworm antigen in dogs is more sensitive than screening for microfilaremia and, in addition, can detect occult infections. Heartworm antigen is first detectable at ~5 mo after infection and will usually precede microfilaremia by a few weeks; however, this time frame may be shifted later in animals on macrocyclic lactone preventives and those with low numbers of worms. Antigen test formats available include ELISA and immunochromatographic assays. Serum or plasma may be used in all kits, and some may be performed using whole blood. Some test kits can be stored at room temperature, whereas others must be stored refrigerated and brought to room temperature before

use. Batch testing and single sample testing are both available. All of the test kits have very high specificity. False-positive results are most often due to technical problems such as inadequate washing or failure to read the results at the optimal time. Manufacturer's instructions should be closely followed with any of the test formats.

Sensitivity varies from one test to another and is affected by worm load, worm gender (a female antigen is detected, thus male-only infections will not be detected), and maturity of female worms. None of these tests has 100% sensitivity. When unexpected false results are obtained on an antigen test, additional testing, using a different format, is recommended.

After adulticide treatment, antigenemia should become undetectable by 6 mo. However, it can take more than a month for some adult heartworms to die, so a positive antigen test at 5–6 mo after treatment does not necessarily indicate treatment failure. The test should be repeated 2–3 mo later.

Heartworm Antibody and Antigen—Cats:

Heartworm disease in cats is substantially different from the disease in dogs, and recommendations for serologic testing are consequently different. Cats tend to have a much lower worm burden—often only one or two worms. Cats also have single-sex infections more frequently than do dogs. Circulating microfilaremia is rare in cats, and microfilariae have a shorter life span. These differences are often attributed to a more effective feline immune response to heartworm infection. However, heartworms can cause serious disease in cats.

Heartworm antigen tests are less sensitive for detection of infection in cats than they are in dogs, with a reported sensitivity of 50%–80%. Therefore, a negative antigen test does not exclude heartworm infection. Antibody testing is also available and can be useful as a screening test, but the presence of antibody does not confirm feline heartworm disease. Transient exposure to larvae will stimulate production of antibody; many early infections are cleared spontaneously, and adult heartworms never develop. A combination of testing for both heartworm antigen and anti-heartworm antibody results in much higher sensitivity and specificity than using either test method alone. Combination testing is warranted in cats with clinical signs of heartworm disease when results of a single test are not conclusive.

Test kits for detection of heartworm antigen and anti-heartworm antibody in cats are marketed in several formats. These can use either plasma or serum and are qualitative or semiquantitative.

Canine and Feline Pregnancy

Diagnosis—Relaxin: The only known pregnancy-specific hormone in the bitch and queen is relaxin, which is produced by the placenta when a fertilized egg is implanted. Relaxin is first detectable in the plasma around day 20–25 after fertilization. It is not present in pseudopregnant or nonpregnant bitches or queens. Relaxin levels peak by approximately day 40–50 of gestation and drop at parturition, but they may remain detectable for up to 50 days during lactation. In-clinic test kits to measure relaxin include microwell ELISA and immunomigration qualitative tests requiring serum, plasma, or whole blood. The assays appear to have very good specificity, ie, a detectable level of relaxin is not found in nonpregnant animals. False-negative results have been reported in some bitches carrying very small litters or in those with one or more nonviable puppies.

Canine and Feline Luteinizing Hormone—Ovulation Timing and Ovariectomy Status:

In the bitch, serum luteinizing hormone (LH) is normally present in very low levels except for a dramatic rise just before ovulation.

● Ovulation occurs 2 days after this LH surge, and the LH level returns to baseline within 24–40 hr of peaking. Serum progesterone levels begin to rise at the time of the LH surge. A bitch will be fertile between 4–7 days after the LH surge, with the most fertile period on days 5 and 6. In addition, the LH surge determines the gestation period, with parturition occurring between day 64 and 66 after the surge. The LH surge may occur anywhere from 3 days before to 5 days after the onset of estrous behavior, so it cannot be reliably predicted by behavior.

Ovulation timing by measurement of LH requires daily testing, which usually begins when >50% of vaginal epithelial cells are cornified, based on vaginal cytology. There is occasionally a false LH peak not followed by ovulation, but it will also not be followed by an increase in progesterone. For that reason, assays of both LH and progesterone are recommended for most accurate ovulation detection. An increased LH concentration not followed by increased progesterone levels is considered a proestrus fluctuation, and testing for ovulation should continue.

A currently available in-clinic kit to measure LH concentrations in serum is essentially qualitative, with a serum level of <1 ng/mL being read as negative and a level of >1 ng/mL considered positive. The test is an immunochromatographic assay.

Ovariectomized bitches and queens have serum concentrations of LH >1 ng/mL. Because this LH concentration is also seen in intact bitches about to ovulate, a single high LH concentration does not confirm reproductive status, but a low LH concentration indicates a nonovariectomized animal.

Canine Ovulation Timing—Progesterone:

Serum progesterone begins to increase after the LH surge with a modest increase on the day before ovulation and a further increase to 4–10 ng/mL on the day of ovulation. Progesterone continues to increase and stays increased throughout pregnancy or diestrus. As the rise in progesterone is more constant compared with LH, daily testing is not necessary. It is recommended that testing begin in late proestrus and continue every 2–3 days until a high range is reached, indicating ovulation.

The test kits for in-clinic progesterone testing are semiquantitative ELISA with preovulatory concentrations designated according to the kit used. Some kits are designed to give two additional progesterone ranges (intermediate and high), whereas others indicate only preovulatory and “ovulatory day or later” levels. In comparison with other test methods, the in-house test kits are less accurate, particularly in the range of roughly 1.5–10 ng/mL, which is the range of interest for earliest detection of ovulation. Accuracy is greater at higher progesterone levels. As mentioned above, measurement of both LH and progesterone is recommended for most accurate breeding management.

Thyroxine: Assay of total serum thyroxine (T_4) may be used as a screening test for canine hypothyroidism or as a diagnostic test for feline hyperthyroidism. (See *also* THE THYROID GLAND, p 552.) In addition, T_4 concentrations are measured when monitoring therapy for hypo- or hyperthyroidism. An in-house ELISA test kit, which uses an additional instrument to read results, provides semiquantitative information about T_4 concentration in canine and feline sera. The assay is run at one of two “dynamic ranges,” depending on the predicted range of results. Published studies comparing this assay with other test methods for T_4 vary in their conclusions. It is recommended that T_4

concentrations be periodically measured in stored pooled serum of cats and dogs to monitor whether assay performance is consistent. It is probably still better to use a commercial laboratory for thyroxine measurement.

Almost all (99%) of total T_4 is bound to protein in the blood and therefore not biologically accurate. Free T_4 levels are a more accurate test of thyroid function in cats and dogs.

Foal Immunoglobulin (IgG): Measurement of foal serum IgG concentration within the first 24 hr after birth can be useful in preventing disease related to failure of passive transfer of IgG in colostrum from mare to foal. Use of foal-side testing procedures can facilitate prompt diagnosis and treatment. A foal serum IgG level of >800 mg/dL is generally considered optimal, with <200 mg/dL indicating failure of passive transfer. Concentrations of 200–800 mg/dL are considered evidence of partial transfer.

Although radial immunodiffusion is considered the most accurate test for IgG concentration, it takes much longer (5–24 hr) than many of the other test methods and thus is not as useful as an indicator of the need for therapeutic intervention. More rapid screening tests include the zinc sulfate turbidity test, glutaraldehyde clot test, and ELISA test kits.

The zinc sulfate test estimates IgG in serum based on its precipitation when added to a zinc-containing solution. Turbidity generally becomes visible when IgG levels are 400–500 mg/dL. This test takes ~1 hr and may be performed with zinc sulfate solutions made in the clinic, or reagents for the test may be purchased as a test kit.

The glutaraldehyde clot test requires the addition of 1 volume of serum to 10 volumes of 10% glutaraldehyde and examination of the tubes at timed intervals up to 60 min. The presence of IgG in the serum causes a solid clot to form in the tube. Clot formation in <10 min generally correlates to an IgG concentration of >800 mg/dL, whereas a positive reaction within 60 min is interpreted as an IgG concentration of >400 mg/dL. Both of these test methods use serum, rather than plasma, so time for the blood to clot and separation of serum must be added to the time needed to perform the test.

ELISA test kits for in-house or foal-side testing can use either serum or whole blood as the sample and take ~10 min. Most are semiquantitative, with color changes corresponding to IgG concentrations of <400 mg/dL, 400–800 mg/dL, or >800 mg/dL.

One quantitative handheld colorimetric immunoassay is currently available.

Reports of sensitivity and specificity among these methods vary. In general, sensitivity in identifying foals with IgG concentrations <400 mg/dL appears to be acceptable for all methods. Thus, there are few foals with total failure of passive transfer that would not be identified by any of these methods. Specificity is less acceptable for some of the methods, and treatment of some foals that did not need it might be instituted based on the results.

Calf Immunoglobulin: Measurement of IgG concentration in neonatal calf serum is important for the same reasons described for foals. However, IgG levels in calves are different from those in foals, with $>1,000$ mg/dL considered evidence of adequate passive transfer and $<1,000$ mg/dL indicating failure of passive transfer. Radial immunodiffusion is the gold standard for accurate measurement of serum IgG in calves (as in foals), but the length of time required to complete this assay makes it less useful than other methods. Other methods include zinc sulfate and sodium sulfite turbidity tests, glutaraldehyde coagulation test, measurement of total serum solids by refractometry, and a lateral flowthrough ELISA test kit.

The sodium sulfite and zinc sulfate turbidity tests are both based on the precipitation of high-molecular-weight proteins in these solutions. Serum is used as the sample, and tests are read after 15–30 min of incubation. Results of these tests vary in sensitivity and specificity depending on the endpoint chosen, and technical difficulties with reagents can decrease test performance. The glutaraldehyde clot test is performed as in foals, with no clot formation at 60 min indicating failure of passive transfer.

Measurement of serum total protein by refractometer is a fairly reliable indicator of adequate passive transfer in healthy, well-hydrated calves. A level of 5.2 g/dL is roughly equivalent to an IgG concentration of 1,000 mg/dL.

A commercially available ELISA test kit uses serum as the sample and takes ~20 min. The assay is qualitative in that it indicates an IgG concentration of $>1,000$ mg/dL or $<1,000$ mg/dL. Sensitivity and specificity are reasonably good, and this test is less influenced by factors such as calf dehydration or reagent instability than some other methods. Manufacturer recommendations for storing and using the kits must be followed.

DIAGNOSTIC IMAGING

RADIOGRAPHY

Radiography comprises the majority of diagnostic medical images generated in veterinary practice, but other imaging modalities such as ultrasonography, CT, MRI, and nuclear imaging are also very important and commonly available in specialty practices and academic centers. Imaging provides a large amount of information by noninvasive means. It does not alter the disease process or cause unacceptable discomfort to the animal. Although radiography itself is painless, sedation is often desirable to reduce anxiety and stress associated with the procedure, to promote acquisition of good diagnostic studies with minimal repeats, and to control pain associated with manipulation in animals with painful disorders such as fractures and arthritis.

Equipment: Radiographs are made using a specialized type of vacuum tube that produces x-rays. The tube current, measured in milliamperes (mA), and voltage, measured in kilovolts (kV), determine the strength and number of x-rays produced and are two of the three exposure factors that can be set on most x-ray machines. Kilovoltage potential (kVp) is the highest potential voltage achieved at any given kV setting.

Higher kV settings produce more penetrating beams in which a higher percentage of the x-rays produced penetrate the subject being radiographed. There is also a decrease in the percentage difference in absorption between tissue types. This results in decreased contrast (long-scale contrast) on the final image. High kVp techniques are most useful for studies of body regions with many different tissue densities (eg, thorax). Higher kVp techniques are appropriate for larger and thicker animals with limitations. Increasing kV is not a linear function, and small increases in kVp settings may substantially increase the number of x-rays penetrating the animal. However, for a number of reasons relating to the production and absorption of x-rays, this effect is much less dramatic above 85 kVp.

Increasing the mA setting on the machine increases the number of x-rays produced. The energy spectrum of the x-ray beam is

essentially unchanged, as are the relative numbers of x-ray photons penetrating tissues of different densities such as bone, soft tissue, and fat. However, the amount of darkening on the image is related to the total number of photons reaching it. Therefore, increasing mA increases image contrast. Changes in mA settings are relatively linear; increased contrast is desirable when tissue densities are similar (eg, soft-tissue components of the musculoskeletal system). However, increasing mA generally results in more heat loading on x-ray tubes, thus limiting exposure times and reducing tube life.

The third major parameter in making a radiographic exposure is exposure time. Increasing the exposure time increases the number of photons produced and hence the darkness of the image. For exposures in the general diagnostic range, this is a linear function; as is the case with increasing mA, increasing exposure time generally results in greater heat loading of the x-ray tube than increasing kVp, once again potentially shortening tube life.

All three of the above parameters are interdependent, with exposure time and mA so much so that the term milliamperereconds (mAs) is usually used to indicate the product of these two factors. Increasing the mA and decreasing the exposure time by a proportionate amount results in a radiograph less likely to be degraded by motion. As a rule, it is best to minimize the exposure time but maintain an appropriate mAs and scale of contrast. Increasing kVp increases the number of photons penetrating the subject and so darkens the image. This effect can be used within limits to correct an underexposure. The converse is likewise true.

When correcting a previously unsatisfactory image, underexposure or overexposure should be corrected for by adjusting the mAs when examining areas of high contrast (skeleton) or by adjusting the kVp when examining areas of low contrast (thorax). This will maintain the same relative contrast for that anatomic area while adjusting the film darkness.

Establishing a technique chart to take radiographs makes it easy for the operator to arrive at a technique by simply correcting a standardized protocol for the size of the animal being examined and the anatomic

area under consideration. It also ensures that radiographs of the same anatomic region will have a consistent appearance from animal to animal. A technique chart must be made for each machine. However, some generalizations can be made. Exposure factors for the thorax should have mAs values ≤ 5 unless the animal is very large. Values of 10 for the abdomen and 15–20 for skeletal studies are appropriate. In many modern x-ray machines, the technique chart is built into the machine. The operator need only enter the species, body part, and thickness, and the machine automatically sets the technique. This is convenient and reduces mistakes in technique, but the settings may need to be altered to suit the specific equipment, film-screen (detector) speed, and the viewer's preferences (eg, contrast level).

Automatic exposure control (AEC) is a system in which the operator sets the kVp and mA, and the machine terminates the exposure at the appropriate time. If used properly, this system results in nearly identical image exposures between animals. However, appropriate kV settings are needed, and consistent animal positioning is critical. Identical positioning between animals is required to achieve identical images. Placing the heart or lungs over the AEC sensor results in radically different appearing radiographs. AEC is probably most effective when large numbers of images are being done of the same anatomic area by the same personnel.

X-ray machines are equipped with collimators that allow adjustment of the size of the beam to the size of the area being radiographed. This reduces the amount of scatter radiation generated, improving image contrast and detail. Scatter radiation is also the major source of radiation exposure to operators, so proper collimation is important to reduce this risk.

When a radiograph is made, some of the x-rays are scattered. When the object being radiographed is ≥ 10 cm thick (15 cm for digital systems), scattering becomes a problem by causing unwanted exposure of the x-ray film. A grid, which is a thin plate made up of alternating thin strips of lead and plastic, can be placed between the animal and the film to reduce the scattered x-rays from exposing the film. The ability of a grid to remove scattered radiation is measured by the grid ratio. The grid ratio is determined by the height of the lead strips divided by the distance between them. A grid with an 8:1 ratio will eliminate more scattered radiation from exposing the film than will a grid with a 6:1 ratio if both have

the same number of lead lines per centimeter.

Digital recording is rapidly increasing in usage, but radiographic images have traditionally, and still are, commonly stored on specially optimized film. However, even the best silver halide film is relatively insensitive to x-rays. For that reason, the x-ray film is usually placed between specially designed phosphorescent screens—panels composed of microscopic phosphorescent crystals embedded in a plastic matrix that directs propagation of the phosphorescent light toward the film. These screens are much more sensitive to x-rays than is film. When the x-ray strikes a crystal, it causes the crystal to phosphoresce, and the light exposes the film secondarily. This process of recording the x-ray image is much more efficient than using film alone and markedly reduces radiation exposure to the subject (sometimes by a factor of 100 or more) and the operator. It also reduces the amount of scatter radiation recorded on the image. The screens and film are contained in a lightproof cassette, which is transparent to x-rays.

Screens and film must be matched for spectral emission and sensitivity. Films produced by one company are generally not optimally sensitive to screens made by another, and it is inadvisable to mix screen and film brands. Screen and film combinations come in different speeds. The larger the crystals in a screen are, the more likely it is to interact with an x-ray and the greater the amount of light produced. Unfortunately, larger crystals also produce larger areas of light, which decreases the detail of the film. Likewise, film with larger silver halide grains is more sensitive to the light creating the exposure but also reduces the detail or resolution of the final image. Therefore, fine grain films are matched to fine crystal screens, resulting in very detailed images that take more radiation to produce. The converse is true for large grain film and large crystal screens.

The speed of these combinations is designated by a rating of 100–1,600, with 100 being relatively slow but with very good detail and 1,600 being very fast but with limited detail. Film-screen combinations with speeds of 200–800 are generally used in veterinary medicine; 200-speed systems are used for small body parts and skeletal imaging, whereas 800-speed systems are used for large abdomens in small animals and thoracic radiography in large animals. Choice of the proper speed system for a specific use is based not only on the area

being radiographed but also on the capabilities of the machine. Small, portable x-ray machines can be used for larger body parts with fast film-screen combinations, substantially improving the utility of these machines.

Use of radiographic film is rapidly being phased out except for special purposes, with digital image capture likely leading to a cessation of film production for most purposes. As advances in digital detector systems continue, it is likely that images produced on digital detector plates will be indistinguishable in detail and quality from those acquired on film. It is already becoming difficult to find film cassettes and screens for medical radiography sold by primary vendors.

Darkroom: As digital image capture replaces radiographic film, darkrooms will no longer be required. However, because radiographic film is still used by many veterinary practices, a brief description of darkroom procedures is provided.

Once the film is exposed, it must be processed in a darkroom to make the latent image recorded on the film visible and fixed so that the image remains unchanged once the film is brought into the light. Care should be taken to be sure no exterior light enters the darkroom. Even very small amounts of white light will markedly fog a film and decrease its diagnostic quality. Safelights used to illuminate darkrooms include filters that remove the frequencies of the light to which the film is sensitive, so the film will not be exposed. Films vary in their spectral sensitivity; therefore, when replacing a safelight filter, the spectral requirements of the filter must be specified.

Automatic processing systems improve processing quality and consistency and reduce the processing time compared with traditional hand film developing. Relatively few films processed per week can justify the purchase of an automated processing system. In any case, film processing must be done in strict accordance with the specified time and temperature requirements of the film being used. These requirements have been standardized for many years, and automated systems are designed to meet them.

Whether processing is manual or automated, the chemicals must be handled with care. Contamination of the darkroom with chemicals can ruin film, screens, and clothes. Fumes from the chemicals may be harmful, and some people may be more sensitive than others, especially to the fixer solution. Cross contamination of the

developer solution with fixer inactivates it and requires replacement of the developer. Improper handling of chemicals results in many artifacts on films as well as potential health hazards to the operators.

Filmless Radiography: Image recording systems do not require the use of film, screens, or processing chemicals. They have several advantages over conventional film radiography: 1) radiographs cannot be lost if adequate data safeguards are used; 2) there is no need for film storage and its attendant space and environmental requirements; 3) the process allows for manipulation and enhancement after the image has been recorded; 4) images can be transmitted electronically to a remote location for immediate interpretation; 5) the images are generally available more quickly, usually within 30 sec; and 6) there is no need for a darkroom.

These systems can be divided into two categories: **computed radiography** (CR), in which a semiconductor plate contained in a cassette is exposed in the usual fashion and then read electronically inside a special reader that detects the magnitude of electrostatic charge on each of the semiconductor elements within the plate; and **direct digital radiography** (DR), in which a cesium iodide scintillator array absorbs the x-rays, producing a light pulse detected by a large array (millions) of amorphous silicon photodiode/transistor elements. In both systems, the electrical output from each of the detector elements is proportional to the number of x-rays that strike the detector element and is mathematically quantifiable, hence the term "digital images." In both systems, the data produced are processed by a computer, which generates the image on a monitor according to a previously determined processing algorithm that is specific to the region being radiographed. Processing algorithms are critical to the development of diagnostic images. In many displaced systems, the algorithm can be altered to provide enhancement of various features of the image. The digital images are then stored electronically and made available to any computer with access to the image archive.

The difference between the two systems lies in the intermediate step of exposing a plate in CR, which is then placed in a reader. These plates must be replaced periodically because of wear created during the reading process. There is also the issue of whether the latent image recorded by the reader is an accurate representation of the true image.

The portability of the cassettes is an important benefit in practice situations in which radiographic images are produced in multiple places. CR systems are also still considerably less expensive than all but the simplest DR systems and generally still have higher resolution capabilities, which may be important for imaging smaller anatomic parts.

DR systems are very complex electronically and subject to the same insults as any complex electronic system. They are particularly sensitive to shock and electronic interference. However, when properly cared for, DR systems are durable and reliable. They do not require handling of the image recording plate, which reduces wear and tear on the system. Their main advantage over CR is image display speed. DR systems have been developed that do not require a cable to communicate between the detector and the computer processing the data into an image. The cable has been replaced by wireless communication on specified electrical magnetic frequencies that are unlikely to be interfered with by other electromagnetic devices such as cell phones and electronic equipment. Although they are still much more expensive than systems incorporating a cable connection between the detector and computer, such systems are particularly suited for use in equine ambulatory practices. Images can also be sent to the storage system in a wireless manner in many areas.

The flexibility and reliability of digital radiography systems, whether wireless or wired, have improved to the point that they are almost universally used in human radiology departments as well as in many veterinary hospitals. As DR systems grow in capability, reliability, ease of use, and resolution, and decrease in cost, it is expected they will eventually replace both CR and traditional film systems. Although currently DR still cannot match the spatial resolution of either standard speed film or CR systems, newer systems are narrowing the gap. This low spatial resolution is offset to a large degree by improved contrast resolution. Because of their inherent high contrast, direct digital systems are also becoming the choice imaging device for very large animals.

The advent of digital imaging has led to the development of special image storage systems and formats. The data stored on computers must be protected from loss and corruption. Loss of data can be guarded against by storing identical sets of data on different computers in different geographic

locations and/or by copying the data files to optical storage media that are then kept in a safe location. Protection of the data from corruption is a more thorny issue. Because images stored in a digital format are easily manipulated by various computer programs, it is possible that they could be altered (accidentally or deliberately) to reflect a different situation than the actual one. For this reason, many electronic image formats are not recognized as legal documents and are not acceptable in a court of law. Because of this potential for alteration or abuse, a special medical image format has been developed and agreed on by the American College of Roentgenology, the American College of Veterinary Radiology, and others as the standard format for medical image generation and storage. This is the Digital Imaging and Communication in Medicine (DICOM) III format. The key feature of this format is the presence of a hidden header in the image file that records all manipulations of the image or the header each time the image is saved. The header also contains a large amount of information about the patient and production factors of the image, which must be specified before creation of the image. This makes accidental or malicious manipulation of the image much easier to trace. Another and even more important benefit of the DICOM III format is that it makes images easily transferable to other sites for referral interpretation or patient referral. No digital imaging system should be purchased that does not conform to the DICOM III standard.

A common misconception associated with digital radiography is that it results in decreased radiation requirements to provide a diagnostic image. Although there has been some progress in this direction, most current digital radiography systems require essentially the same amount of radiation to produce a diagnostic image as with film. The computer system will attempt to reconstruct the image with the proper level of contrast and edge enhancement; however, data poor images will often lack detail despite this enhancement.

Animal Restraint: Animals must be adequately restrained and positioned to obtain quality radiographic images. People dressed in appropriate protective apparel may manually restrain animals; however, manual restraint should be kept to a minimum. In some states, manual restraint is not allowed except under explicitly defined circumstances. Sedation or short-acting anesthesia is often necessary

and usually desirable if medical circumstances permit it. Chemical restraint lessens the need for and intensity of manual restraint, which leads to fewer poor or unacceptable radiographs and usually shortens the time required to complete the examination. In many instances, animals can be restrained and positioned using sandbags, tape, and foam pads. With some practice, it is often possible to complete the radiographic examination in essentially the same time it could have been performed using manual restraint, with the added benefit that the animal is less likely to injure personnel or itself.

Animal motion may also be minimized by decreasing exposure time and maximizing mA to achieve the required mAs for the body region examined. Other technical adjustments, such as increasing the kVp or shortening the film focus distance, may be made in some cases. However, major changes in film focus distance will likely cause serious degradation of the image. In most instances, it is preferable to chemically immobilize the animal as long as there is not a medical contraindication.

Paradoxically, the development of DR systems that allow images to be viewed within 30 sec of production has led to an increase in the number of radiographic images typically produced. Because the images do not have to be processed in a darkroom or through secondary systems such as in CR, individuals making the images often attempt to improve positioning of the animal multiple times. Particularly in instances when the animal is being manually restrained, there is a proportional increase in radiation exposure to both the animal and the holders. This can be avoided by taking a few extra seconds to properly position the animal for the first image.

Proper positioning is also important to maximize the diagnostic content of the x-ray examination. In many cases, improper positioning or radiographic examination can result in a misdiagnosis or inability to appreciate major lesions. Perhaps the best example of this is in thoracic radiography. Both right and left lateral recumbent radiographs are recommended in dogs and cats. This is done because positioning of the animal on its side results in rapid relocation of fluids to and atelectasis of the downside lung. The result is compression and increased radiographic opacity of the dependent lung. Soft-tissue nodules, sometimes of considerable size, can be obscured by this phenomenon. Similarly, lesions affecting the pylorus may be more evident on a left

lateral radiographic examination of the abdomen than on a right lateral. Another example of positioning affecting interpretation is frequently encountered when evaluating the coxofemoral joints for hip dysplasia in dogs. If the legs are excessively abducted, the femoral necks will appear thickened, mimicking the production of osteophytes and potentially leading to a misdiagnosis. Radiography of the spine without the aid of anesthesia in an acutely paraparetic or paraplegic animal may result in inability to properly position the animal for optimal visibility of vertebral structures because of the pain such positioning produces.

Radiation Safety: Radiographic examinations must be performed with proper respect for radiation safety procedures. Diagnostic x-ray machines are potent sources of radiation and can, if improperly used, result in injurious exposure to personnel over time. The exposure factors used in modern x-ray systems are substantially lower than those used in the past but can still result in injury. It is never acceptable to hold animals without the use of lead-impregnated aprons and gloves to decrease exposure to the hands and body of personnel from scattered radiation. Leaded gloves should not be used within the primary beam of the x-ray machine. These gloves and aprons reduce exposure from scatter radiation by a factor of ~1,000 but reduce exposure from the primary beam by only a factor of ~10. Thyroid shields are considered mandatory, and eye shields in the form of lead-impregnated plastic "glasses" are also recommended, especially when radiographing large animals, because the exposures used are sometimes quite high and the orientation of the beam is more likely to be horizontal. Upper limb, cervical spine, and skull studies in horses are particularly likely to result in substantial exposure to anyone holding the film/detector or the horse.

Proper collimation of the x-ray beam is an important and integral part of radiation protection. If the x-ray beam extends beyond the animal, then that radiation contributes to increased scatter radiation and personnel exposure. Any image in which the entire field of the detector or film is exposed is probably under-collimated, unless the animal extends to the limits of the detector. In addition, with digital radiography systems, excessive amounts of exposure outside the subject can result in false interpretation of the data by the reconstruction algorithm and substantially

degrade image quality. If this occurs, the exposure must be repeated with proper collimation to achieve an acceptable image. In most instances, the x-ray beam should be collimated to ~1 cm outside the subject limits to provide optimal image quality and radiation protection for personnel.

Pregnant women and any personnel <18 yr old should refrain from direct involvement in taking radiographic images whenever possible. If a pregnant woman is directly involved in taking radiographs, she should wear an apron that completely encircles her abdomen.

Although federal and state authorities have set maximal limits for both extremities and whole-body radiation exposure for occupationally exposed personnel, the principal of "as low as reasonably achievable" (ALARA) should always be adhered to. The currently set limits allow occupational whole-body exposure to be roughly the same as that which occurs from environmental sources. However, in many veterinary teaching hospitals with large radiographic case loads, the occupational exposure is held to <10% of the permitted values by use of proper protective equipment and radiographic techniques. There is no reason for veterinarians or technicians in private practice to ever receive exposures approximating the allowed limits unless they are heavily involved in specialized interventional radiography.

Individuals involved in taking radiographic images should be monitored for radiation exposure. This is essential to identify and correct conditions that can result in excessive radiation exposure to personnel. Monitoring of exposure also provides evidence of proper adherence to radiation safety standards if questions arise as to whether an employee's medical condition could be related to radiation exposure. Several companies provide this service for a relatively nominal fee.

Interpretation of Images:

Radiographic images are complex two-dimensional representations of three-dimensional subjects that are generated in a format unfamiliar to the average individual. Substantial experience and attention to detail is required to become proficient in interpretation. The start of radiographic interpretation is a properly positioned and exposed study. Studies that are poorly or inconsistently positioned are difficult to interpret, and improper technique further decreases the amount of information obtained from the radiograph.

Although interpretation is aided by experience, conscious use of a systematic approach to evaluation of the image will improve the reading skill of even very experienced individuals and ensure that lesions in areas not of primary interest or near the edge of the image are not missed. However, many studies have shown that experience is the best teacher with regard to evaluation of radiographs. So, although anyone will become more adept at image interpretation with time, those individuals who interpret large numbers of images will be the most proficient. Even proficient individuals can miss lesions that are unfamiliar to them or so-called "lesions of omission." A lesion of omission is one in which a structure or organ generally depicted on the image is missing. A good example of this is the absence of one kidney or the spleen on an abdominal radiograph. Therefore, particular attention to systematic evaluation of the image is very important. It is perhaps best to begin interpretation of the image in an area that is not of primary concern. For instance, when evaluating the thorax of an animal with a heart murmur, the vertebral column and skeleton should be evaluated first because if a substantial lesion is identified for the heart, it is possible that the skeletal structures may not be examined.

It is essentially impossible to evaluate radiographs without a preexisting bias as a result of knowledge of the history, physical examination findings, and previously performed laboratory results. This bias can easily promote under-evaluation of the image by focusing on only the area of interest associated with the bias.

Interpretation of radiographic images depends on a pleural knowledge of anatomy and understanding of disease pathology. Anatomic changes, such as in size, shape, location/position, opacity, and margin sharpness represent the basis of radiographic interpretation. In addition, the degree of change, whether generalized throughout an organ or associated with other abnormalities, must be evaluated. The presence of lesions that do not affect the entirety of an organ, such as focal enlargement of the liver or focal opacification of the lung field, are strongly suggestive of localized disease such as tumors or bacterial infections. Conversely, lesions causing generalized change throughout an organ such as the liver or kidneys are most suggestive of a systemic disease such as viral infections or toxicities. Combinations of lesions in different locations or organs also help narrow down the potential

diagnosis. Careful attention to the basic principles of interpretation and use of a careful systematic approach will often provide answers not readily apparent on initial examination.

Once all of the lesions on the study are identified, a rational cause for those lesions can be formulated. The maximum amount of information is derived from the radiographic study when interpretation is done in light of the clinical and clinicopathologic information available. In this way, the most likely cause for the animal's condition can be determined. However, many diseases can cause similar radiographic lesions, and radiographs must be interpreted in light of the entire gestalt of lesions present and not based on any single lesion if multiple abnormalities are present. In many cases, it is appropriate and advisable to seek the opinion of a radiologist for interpretation of radiographic images, particularly as the number of radiographic studies available and potential diagnoses proliferate.

Contrast Procedures: Radiographic exposure of film alone lacks sufficient contrast to evaluate many structures; therefore, contrast procedures are used to increase the native contrast of organs and lesions, to separate them from surrounding tissues. Contrast media are radiopaque compounds that have extremely low toxicity, although there are well-recognized hemodynamic alterations seen after administration of IV contrast agents. These consist of primarily a reflex hypotension followed by a rebound mild hypertension. In extreme cases, the hypotension can lead to vascular collapse and even anaphylaxis. This effect is thought to be primarily associated with the hypertonic nature of ionic contrast agents and is markedly less evident when nonionic agents are used. For this reason, nonionic agents have almost completely replaced the ionic agents as IV contrast material. IV and intra-arterial contrast agents are generally iodine based and increase the opacity of the blood, making vascular structures visible. Iodinated contrast agents are cleared primarily by the kidneys, making the collecting system of the urinary tract visible. Orally administered agents, primarily barium sulfate-based compounds, outline the mucosa and lumen of the GI tract. Intrathecal contrast agents are also iodine based and allow evaluation of the spinal cord and meninges. Many of these contrast procedures have been largely supplanted by modern imaging procedures, but many of them are still the best way to image the

structures they are designed to evaluate and should not be forgotten if modern imaging procedures fall short. Many contrast procedures do not require special equipment and can be performed in the average veterinary practice, but interpretation is best performed by someone with extensive experience and training in the interpretation of radiographic images.

ULTRASONOGRAPHY

Ultrasonography is the second most commonly used imaging format in veterinary practice. It uses ultrasonic sound waves in the frequency range of 1.5–15 megahertz (MHz) to create images of body structures based on the pattern of echoes reflected from the tissues and organs being imaged. Several types of image formats can be displayed. The most familiar one (and the one that creates the actual image of anatomy) is B-mode grayscale scanning. The sound beam is produced by a transducer placed in contact with and acoustically coupled by means of a transmission gel to the animal. An ultrashort pulse of sound is directed into the animal, after which the transducer switches to the receive mode. Echoes occur as the sound beam changes velocity while passing from a tissue of one density to one of another density, even when the change occurs at nearly microscopic levels. The greater the change in velocity, the greater the strength of the echo. A small percentage of these echoes are reflected back to the transducer, which then reconverts the energy of the echoes into electrical impulses recorded by the computer in the ultrasound machine. The strength of the echo, the time required for the echo to return after the pulse, and the direction the sound beam that was sent are all recorded. Using information from multiple echoes, the machine creates an image that represents the appearance of the tissues when cut in the same plane on an anatomic specimen. In modern scanning systems, the sound beam is swept through the body many times per second, producing a dynamic, real-time image that changes as the transducer is moved across the body. This real-time image is easier to interpret and allows the examiner to scan continuously until a satisfactory image is obtained. The image may then be frozen and recorded in a digital format, which also allows for recording of short segments of the real-time scan. As for radiography and all other medical imaging systems, the standard, accepted, legal format for digital images is the DICOM III standard.

Ultrasonography cannot be used to scan gas-filled or bony tissues. The sound beam is totally reflected at soft tissue/gas interfaces and absorbed at soft tissue/bone interfaces. Gas and bone also "shadow" any other organs beyond them. Bowel gas can inhibit imaging of adjacent abdominal organs, and the heart must be imaged from locations that do not require the sound beam to pass through the lungs.

Sonographic imaging is also limited in regard to the depth of tissue that can be examined. Most scanners will display tissues to a depth of ~24 cm, but the image is often quite noisy at that depth. This is because most tissue echoes do not return directly to the transducer but are reflected in some other direction. By a depth of 24 cm, the loss of energy from the sound beam results in echoes so weak that the scanner cannot separate the returning echoes from the background electronic noise. In addition, some echoes that are not directly reflected may return to the transducer by reflection from a tissue outside the beam path. Such echoes require longer to return to the transducer and are depicted at a spurious location, adding noise to the image. Low-frequency transducers can scan deeper than high-frequency transducers, but resolution is decreased. There is much less loss of beam intensity in fluid media such as the urinary bladder, so if the beam passes through such a fluid media, the maximum scanning depth may be increased at the expense of temporal resolution.

Although ultrasound can be used to evaluate most soft tissues, the heart and abdominal organs still constitute the majority of examinations performed in small animals. In scanning of the abdomen, the abdominal structures should be systematically evaluated. Each sonographer develops his or her own system of completely evaluating the abdomen. Systematic evaluation ensures that all structures are scanned. In the past, organs such as the adrenal glands and pancreas were seen only if diseased and enlarged, but modern ultrasound machines operated by an experienced sonographer produce images of such quality that the normal adrenal glands, pancreas, and lymph nodes can be imaged.

Ultrasonography also is widely used to evaluate the soft tissues of the musculoskeletal system. In Equidae, ultrasound is used to detect and evaluate the presence of tears in the tendons and ligaments of the legs. Examination of joints and the margins of bones around the joints in both large and small animals is also widely performed and

yields information not available from standard radiographic evaluation. Of course, ultrasound cannot be used to evaluate the bones themselves, so the two imaging methods are complementary. In small animals, soft-tissue lesions of the ligaments, tendons, joint capsule, and articular cartilage of the shoulder and stifle joints are readily detectable by an experienced examiner. Most joints and muscles can be evaluated by ultrasonography if the operator is familiar with the normal anatomy and the manner in which pathology of those structures is manifest on the image.

Changes in the size and shape of organs, tissues, and structures are evident in most cases, but evaluation of the echo pattern is based on comparison with that of other organs and tissues the examiner has scanned in other animals. The person evaluating the scan must have a firm idea, developed from experience and comparison with known normals, of the normal echo pattern for each organ scanned with each transducer. The echo pattern will change between transducers because of changes in axial and transaxial resolution as well as transducer design. Comparison of the echogenicity of several tissues must be made, because any organ may have increases or decreases in the echogenicity of its parenchyma. Diseased organs may be either uniformly altered in echogenicity or exhibit focal or multifocal changes. Focal changes are usually easier to detect than uniform changes. Sonographic lesions are sometimes quite characteristic of a given disease process, but more often the changes are nonspecific. Although ultrasonography can be quite sensitive to detection of disease, the changes are not specific for a given disease in most cases unless a characteristic change in anatomic presentation is detected along with changes in echogenicity.

Ultrasound technology has improved the ability of sonographic examinations to detect diseases previously not well characterized by sonographic evaluation. Pancreatitis is a primary example, and in the past 10 years, sonographic evaluation of the pancreas has become a mainstay of assessing animals with suspected pancreatic disease. However, it does not always agree with clinical pathologic evaluation or physical examination. In some cases, the physical examination and pathologic data will suggest pancreatitis, but it is not detected on sonographic examination. This is probably due to the great difficulty of interrogating the entire pancreas using

ultrasound. In other cases, chronic pancreatitis may be indicated by the sonographic examination but poorly characterized by clinical pathologic data because of the chronic status of the disease. Cushing disease is also frequently difficult to interpret on the basis of sonographic examination or any other imaging modality because of the problems of benign adenomas that have no clinical significance in the adrenal glands and because in true Cushing disease the adrenal glands are being overdriven by a pituitary adenoma and are not themselves structurally abnormal. Other instances of increased usage of ultrasound are in the evaluation of other soft tissues such as muscle and tendon injuries as well as cartilage injuries in various joints such as the shoulder and stifle.

Ultrasonography can also be used to direct biopsy instruments to acquire tissue for a specific pathologic diagnosis. This obviates the need for an open surgical exploration in many cases. Lesions buried within large organs such as the liver and kidneys that might not be detectable at surgery may be detected and biopsied with ultrasonographic guidance. Presurgical diagnosis permits more thorough and specific planning of surgical procedures and presurgical treatment of lesions. These procedures can frequently be safely performed under heavy sedation and analgesia. Ultrasound-guided biopsy and aspiration of lesions can also be performed in large animals without the need for general anesthesia.

Echocardiography: Echocardiography is ultrasonic evaluation of the heart. In the past, it was done using the M-mode format of displaying ultrasound information. A narrow beam of sound is projected into the heart, and the echo pattern and strength are displayed onto a persistence screen with the x-axis of the display representing time (y-axis is depth), similar to the familiar format of an ECG. The pattern and amplitude of movement of the walls of the chambers of the heart and valves can be evaluated, as well as the size of the respective structures along the path of the sound beam. The M-mode format has very high temporal resolution and thus is especially excluded to evaluation of rapidly moving structures such as heart valve leaflets. Considerable experience is required to obtain and interpret diagnostic studies. The M-mode examination has been coupled with real-time B-mode studies to improve the accuracy of beam placement

and add additional information, such as shape of the chamber.

Ultrasonographic images are also used to acquire quantitative information about cardiac function. Measurement of specified parameters may be made on either the M-mode scan or on the two-dimensional B-mode image. Mathematical formulas are then applied to determine values for cardiac output, ventricular contractility, ejection fraction, ventricular wall stiffness, and other cardiac functions.

Doppler ultrasound makes use of the familiar phenomenon that sound emitted from a moving object such as a train has a different apparent frequency to someone standing still relative to the moving object. If the object is moving away from the observer, the frequency of the sound is lower; conversely, if the emitter is moving toward the observer, the frequency of the sound is higher. The same is true of diagnostic ultrasound. Echoes from moving RBCs change the frequency of the sound reflected back to the transducer. The amount by which the frequency is shifted is proportional to the velocity of the RBCs; whether it is a positive or negative frequency shift is used to determine blood flow direction. This is used to identify valvular regurgitation (insufficiency), increased flow velocity (as in stenosis), or abnormal movement of the blood in the heart or vessels elsewhere in the body.

Doppler signals may be displayed in two formats. In the first, spectral Doppler, a sound beam is used to evaluate a specific small volume within the vessel of interest. This display resembles the M-mode display except that the frequency shift, or velocity, is substituted on the y-axis. It also shares high temporal resolution capabilities of the M-mode format. The second way to display Doppler frequency shifts is to select a larger area of the scan and a real time B-mode image, encoding the velocities and direction as a color spectrum. The color (usually red or blue) depicts blood flow direction, and the hue depicts mean flow velocity. This allows evaluation of larger areas, but at the price of lower temporal resolution. For this reason, color-encoded B-mode flow studies are used to guide placement of spectral sample volumes to acquire more accurate and complete information. Thus, Doppler studies complement and improve the accuracy and specificity of echocardiograms. Quantitative evaluation of spectral Doppler studies also allows the examiner to determine values such as pressure gradients across valves and stenotic areas or resistance to flow of blood entering an

organ. In some cases, abnormal blood flow patterns can be detected before obvious anatomic lesions are present.

Contrast Ultrasonography: Ultrasound contrast agents increase the reflectivity of blood and any tissue through which blood flows. Enhancement of blood reflectivity is usually accomplished by injection or formation of transient microscopic bubbles in the plasma. The increase in echogenicity is related to the amount of blood flowing through the tissue. The bubbles are quickly absorbed into the plasma and therefore do not constitute an embolism hazard. The ability to evaluate the vascularity of a tissue provides additional information about the type of lesion present. For instance, granulomas generally have poorer blood flow than normal tissue and do not enhance as much as the surrounding tissue, whereas tumors may enhance more and retain the contrast for a longer time than the surrounding tissue. Contrast agents hold great promise for improving both the sensitivity and specificity of ultrasonographic examinations. However, they are extremely expensive, which precludes their use in all but special instances or funded research.

COMPUTED TOMOGRAPHY

In computed tomography (CT), an x-ray tube moves around the body and continuously projects a thin fan of x-rays through the body. Electronic detectors opposite the tube continuously monitor the number of x-rays passing through the body and the angle at which the beam is being projected. The number of x-rays reaching the detector changes as the beam passes through different tissues because of the tube movement. A computer mathematically evaluates the data and determines the most probable density of any point within the volume of tissue scanned. The density is generally measured in terms of Hounsfield units, which divide the entire spectrum of possible densities into 4,000 levels extending from a value of $-1,000$ to $+3,000$. Air is considered to have a value of $-1,000$, water is at 0 , and lead or some other heavy metal is at $+3,000$. Because these units represent the degree to which the x-ray beam is attenuated, the image generated is really an attenuation map, which is what is displayed on the monitor and stored as a digital file by the computer. Together, all of the attenuation points make an image of the cross-section of the portion of the body through which the beam is passed. This tomographic image is usually referred to as

a **slice**, and each of the individual attenuation points in the image is referred to as a **voxel** (volume element). The animal is then moved a specified number of millimeters, and the process repeated. By sequentially scanning a body area, the entire volume of interest can be imaged without any superimposition of structures. CT also has much better contrast discrimination than standard radiographs, so structures such as individual parts of the brain or individual muscle bellies are seen as separate and distinct on the CT scan. X-ray contrast media is frequently used to further enhance the contrast between structures and help characterize lesions.

Modern multislice CT scanners can acquire up to 620 cross-sectional images at once; each rotation may be as short as $\frac{1}{4}$ sec. These systems are capable of continuous rotation (helical or spiral scanning), in which motion of the patient through the scanner occurs in concert with the rotation of the scanner. These systems can perform a complete scan of the abdomen or thorax in a person on a single breath hold (~ 10 sec) and with appropriate ECG-based control can provide CT images of a beating heart during all portions of the cardiac cycle. The image reconstruction time is short, and the entire study can be completed in less time than was required to acquire a single image 15 years ago. Some veterinary practices now have 8- to 64-slice scanners installed, and the actual scan takes less time than it takes to position the animal on the scanning table. Even with such extraordinarily fast systems, veterinary patients must still be anesthetized and immobilized to perform most studies, but the period of anesthesia is short and the value of the information derived is great. Although studies have been published in which fully awake or minimally sedated animals were imaged, scans performed in this manner lack controlled positioning and reflect movement and are therefore difficult to interpret. This type of study should be reserved for instances in which the animal is severely obtunded by its medical condition or for the rare instances in which sedation would significantly alter the status of the tissues (such as an attempt to evaluate the effect of drug intervention in an asthmatic cat).

As with conventional radiography, the use of nonionic contrast agents can markedly improve the diagnostic accuracy and sensitivity of CT. For vascular studies, the contrast dosage is also substantially less than that used in conventional radiographic angiography. The utility of contrast enhancement on CT imaging is so important

that nearly all CT studies of soft-tissue structures such as the brain or abdominal organs are contrast enhanced. Obtaining a contrast-enhanced image after a nonenhanced study allows comparison of the two images to give insights into the hemodynamic and physiologic changes present.

Modern reconstruction algorithms also allow three-dimensional reconstruction of structures with a given density. Bones can be depicted without the overlying soft tissues, and vascular structures that have been contrast enhanced can be depicted without any overlying tissues. Newer scanners can produce images of vessels that rival those obtained by conventional contrast angiography.

In addition to some of the imaging procedures unique to CT, this modality is replacing conventional radiography for evaluation of some structures and diseases traditionally assessed by radiography. CT scans of the skull in any species are far more informative and diagnostic than any conventional radiograph because the complex anatomy of the skull, which results in a pattern of overlying structures on a radiograph, is vastly simplified on a CT scan, making the diagnosis much more specific and accurate and improving treatment results. CT scanning is also rapidly replacing myelography for evaluation of spinal cord disease because of its greater safety and speed as well as being able to directly image the discs and vertebrae. CT scanning is also receiving much attention as a screening procedure to evaluate the lungs and other anatomic areas for evidence of distant metastasis in cancer patients. Metastatic lesions in the lung are far more evident at a smaller size on CT scans than on conventional radiographs. If a CT scan is performed after detection of metastatic lesions on radiographs, the CT scan will almost always find more nodules than are evident on the radiographic images.

CT scans of the feet and legs of horses can detect structural changes in bones and hoof structures that are not readily evident on even detailed radiographic images of the same body part. Unfortunately, no scanners currently can scan the abdomen or thorax in adult horses.

CT is also used to guide the acquisition of biopsy and aspirate of samples from many areas of the body, including the lungs and brain, that cannot be approached using ultrasound or other imaging modalities. The same type of approach may be used to perform image-guided therapy of some diseases such as radiofrequency ablation of tumor nodules in the liver. Such

image-guided treatment obviates the need for a surgical procedure, reducing the impact of treatment on the patient.

CT scans are used to detect structural changes deep within the body, including tumors, abscesses, vascular abnormalities, occult fractures, and hematomas. Modern, high-speed scanners are also used to evaluate dynamic physiologic processes such as blood flow, changes in respiratory volume, and intestinal dynamics. The radiologist must have a firm knowledge of anatomy and physiology to ascertain the identity of structures in any plane through the body and evaluate changes in its anatomy or physiology. Knowledge of physiology and artifacts are also important in evaluating CT scans. Extensive experience and training are required to become adept at performing CT procedures and deriving the most information from the images. As the utility and availability of scanners has increased, veterinary medicine has seen a great jump in the number and quality of instruments available for use in veterinary patients.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) is the newest form of imaging in general use today. In this imaging modality, a powerful magnet, up to 60,000 times as strong as the magnetic field of the earth, is used to transiently align the hydrogen atoms in the body with the magnetic field. All atoms with odd atomic numbers are affected, but the effect on hydrogen overshadows the effect on other natural elements within the body. If the hydrogen atoms are then subjected to a radiofrequency (RF) pulse of the proper frequency, the alignment of these atoms is then deflected to one side or reversed. Once the RF pulse is turned off, the hydrogen atoms realign with the magnetic field. The rate at which they do this is restricted by (and characteristic of) the molecule of which they are a part. During this relaxation or realignment phase, the hydrogen atoms emit radio waves that can be detected by highly sensitive equipment. The frequency of these waves depends on the strength of the magnetic field. By using a second set of magnets referred to as the gradients, the magnetic field of the scanner can be arranged in such a way that each small discrete volume (voxel) has a different field strength. Because the RF emitted by the relaxing hydrogen atoms depends on the strength of the magnetic field in which

it is located, each of these volumes can be represented by a unique frequency. Then, by evaluating the signal strength and duration for each frequency, the chemical composition of each voxel can be estimated. In practice this is done by representing the signal strengths for each volume on a monitor, much as is done with CT. The signal strength from each volume element is very small, so many repetitions or pulses of the RF field are required to provide a statistically significant determination of the relative signal strength from the volume elements. Thus, each scanning sequence may require several minutes to perform. Sequential examination of slices through the body is done the same way CT examinations are performed. MRI differs from CT in that the data for all the slices in the volume being imaged are acquired simultaneously; however, previously only one set of planes is acquired at a time, but recent developments in scanner technology allow acquisition of volume data sets. Scans are typically acquired in more than one of the three orthogonal planes, with different magnet pulsing sequences to highlight different types of tissue. Also, unlike CT, MRI scans are seldom reformatted to project oblique planes, although three-dimensional rendering may be done either on the scanner's computer or a stand-alone workstation.

MRI does not use ionizing radiation and thus has gained rapid and wide use in pediatric imaging in human medicine. Although this is less of a concern in veterinary medicine, the ability to obtain diagnostic images without the use of ionizing radiation is desirable for veterinary personnel.

MRI scanners are extremely sensitive to the presence of certain metals such as iron and cobalt. The presence of such materials within the patient can markedly degrade the quality of the image, even to the point that it is not possible to develop an image at all. Although surgical stainless steel now in use has minimal ferromagnetic properties, it can still distort the image somewhat. Even the small amount of iron present in identity chips can produce significant artifacts on the images. For this reason, animals to be subjected to MRI scanning should have radiographs of the area of interest before being placed in the MRI scanner. The presence of metallic foreign material in the GI tract or soft tissues can easily result in a nondiagnostic study. An exquisite example of this is the presence of a steel shotgun or BB gun pellets; the

presence of even a single such pellet may totally degrade the images. Another potential source of such artifacts could be stainless steel sutures or hemoclips. Depending on their chemical composition, such materials may or may not significantly alter the images.

MRI interpretation requires a firm knowledge of sectional anatomy as well as knowledge of the physics of the imaging system. Because this type of imaging is based on chemical composition of the body rather than density, it provides exquisite detail and contrast of body structures. However, the duration of data acquisition limits its use in areas of substantial movement, such as the chest and upper abdomen, although recent improvement in scanner technology has largely done away with this limitation. MRI does not image cortical bone well and therefore is of limited use in the evaluation of bony lesions, although it is quite applicable to imaging of bone marrow and cartilage. Like CT, MRI was initially used primarily for neuroimaging and is still the mainstay of imaging in that area. Another major area of MRI usage is in evaluation of blood vessels deep within the body, particularly those of the legs, neck, and head. Because of its exquisite sensitivity to the changes in tissue organization and composition as well as density, MRI is also used frequently for joint and muscle imaging, where it has become a valuable tool in assessment of joint integrity because of its unique ability to image cartilage and ligaments. This has led to great interest in developing and promoting MRI imaging of equine extremities if the issue of motion can be overcome.

Contrast enhancement of MRI scans is common when imaging the brain and other soft tissues. It can frequently permit the radiologist to make a relatively specific diagnosis regarding the etiology of the lesions seen on the scan. In other instances, the contrast images are the only ones that reveal the presence of a lesion. The agents used are specifically designed for use in MRI and are different from those used in CT and radiography.

In the past, MRI systems were large and expensive to purchase, install, and maintain, but many smaller, low-field-strength magnets are available, including some specifically designed for use in veterinary medicine. Dedicated equine extremity scanners are available, and although these instruments are relatively expensive, they are within financial reach of many large practices, especially

those specializing in imaging and neurology. The use of lower field strengths will reduce the construction requirements of MRI facilities to house these instruments but comes at the price of longer scan times and decreased image resolution.

The length of time required to complete MRI scans and the exquisite sensitivity of MRI to motion dictates that studies be performed under general anesthesia. Because powerful magnets are used, ferromagnetic material may not be brought into the room because of safety considerations. For veterinary patients, injectable anesthesia may be used if special anesthesia machines, oxygen tanks, and monitoring equipment are unavailable. Injectable anesthesia may not be appropriate for all patients, so facilities dedicated to veterinary patients are well advised to have appropriate anesthetic equipment. The cost of such equipment is minor compared with that of developing the MRI facility itself.

Because of their exquisite sensitivity to radiofrequency signals, MRI systems must be shielded from all extraneous signals of this type. This requires installation of specialized shielding material in the walls of the room in which the MRI is located. Further, the larger, more advanced systems with higher field strength typically require liquid helium as a coolant to minimize signal noise from within the machine itself and to maintain a superconductive magnetic field. The construction of an MRI facility must be done under the direction of a qualified architect and engineering firm.

MRI scanners should be operated by technologists specially trained in operation of these instruments. Many factors must be taken into account when preparing an animal for an MRI. This training is not part of either the veterinary curriculum or the veterinary technical curriculum and must be acquired by attending special training sessions or preferably as part of the training program in a school of radiologic technology. Having well-trained technologists to perform these studies will greatly improve the quality of the scans and promote the use of these instruments for a wider variety of imaging applications.

Because of the expense of acquiring and maintaining these instruments (especially those with field strength of 1 Tesla or above), the technical complexity of MRI imaging, and the special training and experience required to interpret the images, MRI scanning systems are generally found only in large private and academic referral specialty practices.

NUCLEAR MEDICINE IMAGING

(Nuclear scintigraphy)

Although it has been around for >50 yr, nuclear scintigraphy is still relatively unused in veterinary medicine. The reason is because it uses radionuclides, which are both expensive and heavily regulated. In addition, the images derived from the studies are physiologic in nature and therefore quite unfamiliar to most veterinarians. This is unfortunate, because nuclear scintigraphy provides information on pathologic and physiologic processes that cannot be obtained by other means.

Nuclear medicine imaging involves dosing the patient with a very small amount of a gamma ray-emitting radioisotope. The location and distribution of the radioisotope within the body is then detected with a gamma camera, a device specifically designed to collimate and detect gamma rays. The isotope may be injected, ingested, or inhaled as appropriate for the study being performed. The radioisotope is usually part of a larger molecule that has a specific affinity for the tissue or organ of interest. For instance, some organic phosphonates have an affinity for bone, and isotopes bound to sulfur colloids will localize in the liver and spleen. Very few radioisotopes have direct affinity for a given tissue; iodine is the notable exception and localizes very strongly in the thyroid. Inhaled gases or aerosols localize in the airways and lungs and may or may not be absorbed into the bloodstream. In veterinary medicine, the most commonly used isotope is metastable technetium 99 (^{99m}Tc), although radioactive iodine, indium, and thallium are also used in specific instances.

The data collected by the gamma camera can be displayed directly on a monitor or projected onto a film or a digital file as a permanent record. Most modern systems send the data to a computer system for analysis, which allows enhancement of count differences and determination of organ margins. The operator can select regions of interest to analyze for isotope content and rate for accumulation over time. When the study uses a radiopharmaceutical that is metabolized or has a limited residence time in an organ, organ function can be determined. These dynamic studies can be used to evaluate the function of organs such as the lungs, kidneys, and heart. Such studies may reveal abnormalities that static forms of anatomic imaging cannot detect. Functional imaging is the great strength of nuclear medicine and allows disease detection earlier and more readily

than anatomic imaging systems. Advanced MRI studies can emulate this functional aspect of scintigraphic imaging in some cases, but those systems are much more limited in scope and availability, as well as costing an order of magnitude more.

Single photon emission computed tomography (SPECT) and positron emission tomography (PET) are advanced scintigraphic imaging techniques widely used in human medicine for detection and evaluation of many diseases. In both of these techniques, a CT-like cross-sectional image based on the deposition of radionuclides within the body is generated. Such images have greater sensitivity than planar images and improved specificity as well.

PET imaging in particular has seen tremendous growth in the last decade and is routinely used in the staging and evaluation of many diseases, especially cancer. This technology, which is based on the use of positron-emitting isotopes of lighter elements such as oxygen, nitrogen, carbon, and fluorine, can evaluate the metabolism and localization of these elements with great sensitivity. PET imaging is available at most academic centers, and its use exceeds that of traditional nuclear scintigraphy in some centers. These instruments are extremely

sensitive and can often define the presence of or characterize the extent of some disease processes long before they can be evaluated by anatomic imaging systems such as MRI or CT. When these images are combined with CT or MRI images, tremendous sensitivity for the detection of numerous diseases results.

The major issue with using nuclear medicine imaging in veterinary medicine is not the availability of gamma cameras or the technical expertise required to operate them. Cameras are readily available on the used market, and training of technologists to operate them is not prohibitively complex. Rather, it is the regulations surrounding the acquisition and use of radiopharmaceuticals. All use must be strictly documented and, unlike in human medicine, the veterinary patient generally must remain in the hospital after the study is performed to allow the agents to be mostly cleared from the body. A second reason for limited use is the physiologic nature of the lesions, which results in images of poor spatial resolution even though they are exquisitely sensitive to some disease processes. The special training required for interpretation of these images is provided as part of a veterinary radiology residency program available at only a few centers.

DISPOSAL OF CARCASSES AND DISINFECTION OF PREMISES

When animals die or are slaughtered on farms, carcasses and parts that are unfit for use as food should be disposed of properly. Safe and environmentally responsible disposal of animal carcasses, whether an individual death or during significant mortality events, is an essential consideration. Premises should be promptly cleaned in a manner that prevents any infectious or toxic health hazard to domestic or wild animals or people. Information on the safe and lawful disposal of carcasses can be obtained from local environmental protection agencies. When the circumstances under which death has occurred suggest a transmissible disease or toxic hazard, the nearest animal health official should be notified immediately.

As general precautions, persons handling carcasses and disinfectants should wear protective clothing and be properly equipped to complete the tasks of disposition and disinfection. The method of disposal should preclude contamination of soil, air, and water. Hides and other parts of animals that have succumbed to infectious diseases or toxins should be safely disposed of and not retained for use.

There are restrictions on carcass disposal for cattle ≥ 30 mo old because of specified risk materials (tissues in which prions that cause **bovine spongiform encephalopathy** [BSE] concentrate). Sheep or cattle diagnosed with or suspected of being affected by **scrapie** (see p 1288) or BSE (see p 1284), respectively,

must not be rendered. The preferred means of disposal for these animals is incineration, although they may also be buried (see below).

Rendering: Ordinarily, rendering is a safe, rapid, and economical method of disposal of carcasses. Renderers are required to use equipment and methods that prevent health hazards. Local regulations specify requirements for transportation of carcasses to rendering plants. During transportation, biosecurity must be considered to avoid spreading infectious agents into the environment.

Burial: When a site acceptable to the local environmental protection agency is available, burial is usually the preferred method of disposal. In selecting a burial site, it is necessary to consider the adequacy of soil depth and to avoid underground electrical cables, water pipes, gas pipes, septic tanks, and water wells. The prevention of secondary toxicosis or exposure to infectious agents to scavengers or groundwater must be considered (eg, the burial of a carcass infected with blastomycosis could potentially contaminate the soil thereafter). The burial pit or trench should be at least 2.3 m wide and 3 m deep (7 × 9 ft). The pit is a cave-in hazard and must not be entered without proper shoring, and any other appropriate precautions should be taken. At this depth, 1.3 m² (15 ft²) of floor space will accommodate a mature bovine or equine carcass, 5 mature pigs or sheep, 100 mature chickens, or 40 mature turkeys. For each additional meter (3 ft) in depth, the number of animals per 1.3 m² of floor space may be doubled. Contaminated litter, soil, manure, feed, milk, or other material should be placed in the pit with the carcasses and covered with at least 2 m (6 ft) of soil. The covering soil should not be compacted. Decomposition and gas formation cause cracking, bubbling, and leaking of fluids from a compacted burial site. The soil should be mounded and neatly graded.

Burning: Burning in an incinerator that is operated in compliance with local laws and ordinances is an excellent means to dispose of one or a few carcasses and is the preferred means for sheep with scrapie and cattle with BSE.

Burning carcasses in an open site should be done only when legally permitted. Burning poultry carcasses should be

considered only when burial is not feasible. The burn site should be away from public view and on flat, open ground that is clear of buildings, hay or straw stacks, overhead cables, and shallow underground pipes or cables. Locations upwind from houses, farm buildings, roads, or populated areas, and those from which precipitation runoff may contaminate the environment, should be avoided.

Carcasses must be placed on a quantity of combustible supporting materials sufficient to reduce them completely to ashes. The material must also be arranged in a manner to permit an adequate flow of air to the fire. Gasoline or other highly volatile combustible liquids should not be used.

To prepare the fire bed, an area of ground should be staked out to accommodate the number of carcasses to be burned: 8 × 3 ft for each mature cow or horse, 5 mature pigs or sheep, 100 mature chickens, or 40 mature turkeys. The fire bed burns best if at a right angle to the prevailing wind.

Under favorable conditions, burning should be complete in 48 hr. Additional combustible material should be added as needed. When the fire has died out, the ashes should be buried and the area cleaned, graded or plowed, and prepared for seeding.

Other Disposal Methods: Composting, fermentation, and dry extrusion methods have been developed to process certain dead animals and animal waste, destroy pathogenic organisms, reduce volume, and produce feedstuffs. Local environmental protection agencies and state agriculture departments should be consulted concerning the acceptability of these and other possible alternative disposal methods.

Disinfection of Premises: Removal and safe disposal of manure, feed, and debris by burial or burning, followed by thorough scraping and cleaning of all buildings and equipment, must precede the application of chemical disinfectant. Except for steam cleaning, cleaning with aqueous solutions is practical only at temperatures above freezing. A cleaning agent such as trisodium phosphate or sodium carbonate dissolved in hot water will facilitate cleaning. All traces of the cleaning agent must be rinsed away with clear water before disinfectant is applied. Provision must be made to contain and safely dispose of cleaning solutions, rinse water, and disinfectant.

Disinfectants recommended for general use on surfaces free of organic matter are

sodium or calcium hypochlorite (1,200 ppm available chlorine), iodine, phenol, and quaternary ammonium compounds. Newer disinfectants use a combination of products (eg, quaternary ammonia and glutaraldehyde) to enhance efficacy. Information on disinfectants for specific animal disease

agents can be obtained from state or federal animal health agencies. Disinfectants should bear the approval statement of the Environmental Protection Agency in the USA or of a similar agency in other countries. Label instructions for application must be followed.

EUTHANASIA

Euthanasia is the term used to describe ending the life of an animal in a way that eliminates or minimizes pain and distress. Animal slaughter, depopulation, and humane killing are distinguished from euthanasia, because they are performed for reasons different than sparing an animal from unresolvable painful or distressful conditions. Euthanasia of animals is a common procedure performed by veterinary professionals, and because of the seriousness of the action, it deserves appropriate consideration. Some of the most difficult euthanasia decisions that veterinarians are required to make involve the euthanasia of healthy animals when no other alternative for their care can be identified. A veterinarian must be fully prepared to speak frankly about the animal's condition and be knowledgeable about all possible alternative care resources when interacting with animal owners, caretakers, and control professionals. Recognizing the importance of a "good death" in the humane termination of an animal's life, many countries and professional organizations have developed guidelines and recommendations for animal euthanasia; some are more specific for certain species and environmental settings. Most recommendations emphasize certain factors that personnel performing euthanasia should consider when selecting the best method of euthanasia. These factors include: 1) ability of the method to induce loss of consciousness and death with minimal pain and distress; 2) time required to induce loss of consciousness; 3) reliability; 4) safety of personnel; 5) irreversibility; 6) compatibility with intended animal use and purpose; 7) documented emotional effect on observers or operators; 8) compatibility with subsequent evaluation, examination, or use of tissue; 9) drug availability and

human abuse potential; 10) compatibility with species, age, and health status; 11) ability to maintain equipment in proper working order; 12) safety for predators or scavengers should the animal's remains be consumed; 13) legal requirements; and (14) environmental impacts of the method or disposition of the animal's remains.

To be able to understand and help others to understand euthanasia, personnel performing euthanasia should be well informed of established definitions of the more important physiologic and psychological states that may be observed during euthanasia. The American Veterinary Medical Association Panel on Euthanasia accepts the following important definitions: 1) anesthetic-induced unconsciousness is the loss of the righting reflex; 2) pain is a conscious experience; 3) distress is an animal's response to stimuli that interferes with its well-being and comfort. Thus, biological functions (urination, defecation), unintentional movements (limb paddling), and vocalizations after administration of an appropriate euthanasia method, and subsequent recumbency are not necessarily signs of perceived pain or distress. Loss of physiologic function and death should occur in the following order to help prevent fear and distress: 1) rapid loss of consciousness, 2) loss of motor function, 3) arrest of respiratory and cardiac functions, and finally 4) permanent loss of brain function. If loss of motor or respiratory and cardiac function precedes loss of consciousness, as might be the case if paralytic agents are used, animals may become fearful and experience distress. In some species, particularly rabbits and chickens, tonic immobility may be induced by fear, and care must be taken to not confuse this behavioral response with loss of consciousness.

In addition to the selection of the method of euthanasia, the euthanasia

administrator should consider the natural behavior of the species. For virtually all species, being placed in a novel environment before euthanasia is stressful. Therefore, a euthanasia approach that can be applied in familiar surroundings may help reduce distress. Gentle restraint, careful handling, and talking during euthanasia often have a calming effect on animals accustomed to human contact. These techniques may also be effective coping strategies with personnel and owners. In some species, sedation may assist in achieving the best conditions. The emotional attachment between animals and their owners or caretakers requires an additional layer of professional respect and care. Discussing euthanasia openly with personnel allows everyone the opportunity to understand that the best interests of the animal,

owners, and caretakers have been considered.

Regardless of the method of euthanasia selected, personnel performing euthanasia must confirm death and dispose of the carcass in a legal manner that does not contaminate food sources or the environment. Confirming death may best be accomplished by an adjunctive method (thoracotomy, decapitation) performed after the loss of consciousness. Using an adjunctive method may be especially important when euthanizing ectothermic animals, because their heartbeat and respiration are difficult to assess.

For a list of acceptable methods and agents for euthanasia of different species of animals, *see* TABLE 3. The AVMA Guidelines for Euthanasia 2013 provide additional details, as well as references for specific technical and safety information.

TABLE 3 AGENTS AND METHODS OF EUTHANASIA BY SPECIES

Species	Acceptable Methods ^a	Acceptable Methods with Conditions ^b
Aquatic invertebrates	S 6.3 ^c : Immersion in anesthetic solution (magnesium salts, clove oil, eugenol, ethanol)	S 6.3: Adjunctive methods (second step) include 70% alcohol and neutral-buffered 10% formalin, pithing, freezing, boiling
Amphibians	S 7.3: As appropriate by species—injected barbiturates, dissociative agents, and anesthetics as specified, topical buffered tricaine methanesulfonate or benzocaine hydrochloride	S 7.3: As appropriate by species—inhaled anesthetics as specified, CO ₂ , penetrating captive bolt or firearm, manually applied blunt force trauma to the head, rapid freezing
Avian species (<i>see also</i> Poultry, below)	S 5: IV barbiturates	S 5: Inhaled anesthetics, CO ₂ , CO, N ₂ , Ar, cervical dislocation (small birds and poultry), decapitation (small birds) S 7.5: Gunshot (free-ranging birds)
Cats	S 1: IV barbiturates, injected anesthetic overdose	S 1: Barbiturates (alternative routes of administration), inhaled anesthetic overdose, embutramide, T-61, CO ₂ ^c , CO ₂ ^c , gunshot ^c
Cattle	S 3.2: IV barbiturates	S 3.2: Gunshot, penetrating captive bolt
Dogs	S 1: IV barbiturates, injected anesthetic overdose	S 1: Barbiturates (alternative routes of administration), inhaled anesthetic overdose, embutramide, T-61, CO ₂ ^c , CO ₂ ^c , gunshot ^c

(continued)

TABLE 3 AGENTS AND METHODS OF EUTHANASIA BY SPECIES (continued)

Species	Acceptable Methods ^a	Acceptable Methods with Conditions ^b
Fish	S 6.2: Immersion in buffered benzocaine or benzocaine hydrochloride, isoflurane, sevoflurane, metomidate, quinaldine sulfate, buffered tricaine methanesulfonate, 2-phenoxyethanol, injected pentobarbital, rapid chilling (appropriate zebrafish/research setting)	S 6.2: Eugenol, isoeugenol, clove oil, CO ₂ -saturated water (aquarium-fish facilities/fisheries), decapitation/cervical transection/manually applied blunt force trauma followed by pithing, rapid chilling followed by adjunctive method (aquarium-fish facilities), maceration (research setting)
Equids	S 4: IV barbiturates	S 4: Penetrating captive bolt, gunshot
Marine mammals	S 7.4: Injected barbiturates (captive)	S 7.4: Inhaled anesthetics (captive) S 7.6: Gunshot, manually applied blunt force trauma, implosive decerebration (free ranging)
Nonhuman primates	S 2.3, S 7.4: Injected barbiturates or anesthetic overdose	S 2.3, S 7.4: Inhaled anesthetic, CO, CO ₂ (as appropriate by species)
Poultry	S 3.4: Injected barbiturates and anesthetic overdose	S 3.4: CO ₂ , CO, N ₂ , Ar, cervical dislocation (as anatomically appropriate), decapitation, manual blunt force trauma, electrocution, gunshot, captive bolt
Rabbits	S 2.4: IV barbiturates	S 2.4: Inhaled anesthetic overdose, CO ₂ , cervical dislocation (as anatomically appropriate), penetrating captive bolt
Reptiles	S 7.3: As appropriate by species—injecting barbiturates, dissociative agents, and anesthetics as specified; topical buffered tricaine methanesulfonate or benzocaine hydrochloride	S 7.3: As appropriate by species—inhaled anesthetics as specified, CO ₂ , penetrating captive bolt or firearm, manually applied blunt force trauma to the head, rapid freezing
Rodents	S 2.2: Injected barbiturates and barbiturate combinations, dissociative agent combinations	S 2.2: Inhaled anesthetics, CO ₂ , CO, tribromoethanol, ethanol, cervical dislocation, decapitation, focused beam microwave irradiation
Small ruminants	S 3.2: Injected barbiturates	S 3.2: Gunshot, penetrating captive bolt
Swine	S 3.3: Injected barbiturates	S 3.3: CO ₂ , CO, N ₂ , Ar, gunshot, electrocution, nonpenetrating captive bolt, manually applied blunt force trauma

Reprinted, with permission, from the AVMA Guidelines on Euthanasia 2013 Edition. **Note:** Initial "S" references with associated numbers in table entries refer to specific areas of more detailed information in the AVMA Guidelines, available at www.avma.org/KB/Policies/Documents/euthanasia.pdf.

^a Acceptable methods are those that consistently produce a humane death when used as the sole means of euthanasia.

^b Acceptable methods with conditions are those that may require certain conditions to be met to consistently produce humane death, may have a greater potential for operator error or safety hazards, are not well documented in the scientific literature, or may require a secondary method to ensure death.

^c Not recommended for routine use.

MEAT INSPECTION

Inspection of meat by qualified individuals to eliminate unwholesome, adulterated, or mislabeled meat or meat products from the food supply protects consumers from the physical, infectious, and toxic hazards that may originate in food animals, the environment, or people. The standard procedures do not cover every possibility concerning the acceptability of carcasses, organs, or other animal parts; personal judgment is also required to ensure that only wholesome, unadulterated product is approved for food. (See also *CHEMICAL RESIDUES IN FOOD AND FIBER*, p 2518.)

Inspection activities are divided into premortem, postmortem, and processing inspection.

PREMORTEM INSPECTION

Premortem inspection is conducted at the abattoir on the day of slaughter to detect and condemn animals that are unfit for slaughter and to note signs or lesions of disease that may not be apparent after slaughter (eg, rabies, listeriosis, or heavy metal poisoning). During inspection, animals should be confined in a lighted enclosure so that they can be clearly observed at rest and in motion. The animals must not be allowed to enter into any area of the facility where slaughtering, dressing, or handling of edible products is performed until they have been inspected and found to be acceptable candidates for human consumption. Gates, chutes, and equipment must be available to segregate abnormal animals for closer examination and proper identification.

Seriously crippled animals, animals commonly termed "downers," and disabled or moribund animals are not acceptable candidates for slaughter as food. Rectal temperatures should be verified on any animal suspected of being febrile. Body temperature should be $<106^{\circ}\text{F}$ (41°C) for pigs and $<105^{\circ}\text{F}$ (40.5°C) for cattle, sheep, goats, horses, and mules. Animals with signs or lesions that do not warrant immediate condemnation can be identified as "suspects" so that their carcasses and viscera can be inspected separately. Certain animals may be retained to allow recovery from minor diseases or to permit depletion of residues of biologic substances and chemicals. Animals that may have been treated with or exposed to

substances that may make the edible tissues unfit for human food should not be slaughtered for such.

Animals that have reacted to a test for anaplasmosis, leptospirosis, or tuberculosis are unacceptable as food. The temperature of bovine tuberculosis reactors should be taken on premortem inspection.

Animals suspected of having a foreign disease or parasite should be held and reported immediately to the nearest federal or state health official.

Animal welfare and humane slaughter concerns are increasingly important to the livestock industry. Slaughtering plants in the USA are routinely observed to ensure full compliance with provisions of the Humane Methods of Slaughter Act of 1978 and related regulations. Humane handling of livestock before slaughter is necessary and includes methods of stimulation, nonabuse by plant workers, provision of food and water, safe pen construction, nonslip floors, and protection from adverse weather conditions.

Most large meat producers require compliance with humane slaughter regulations. Therefore, these animals must be rendered insensible to pain by a single blow, gunshot, or an electrical, chemical, or other method that is rapid and effective before shackling, hoisting, or cutting.

Recognized ritual slaughter methods, such as halal and kosher, are exempted from these requirements.

POSTMORTEM INSPECTION

Animals should be inspected immediately after slaughter and evisceration for possible changes and lesions that indicate unsuitability of the meat for food.

Postmortem examination requires observation of all parts of the carcass, dressing procedures, equipment, and facilities to prevent contamination of edible parts. The inspector must ensure that condemned carcasses and parts are disposed of safely. The following are unacceptable for human food: lactating mammary glands, laryngeal muscles, thyroid glands, and lungs. Brains, cheek meat, and head trimmings from animals that were stunned by lead, sponge iron, or frangible bullets, and carcasses suspected of containing antibiotics, sulfonamides,

or other residues are also unacceptable. CNS tissue and spinal cords must be discarded to eliminate the threat of bovine spongiform encephalopathy in the food supply.

Routine postmortem inspection should include the following procedures.

Cattle: *Head:* Incise and visually examine the left and right atlantal, mandibular, parotid, and suprathyroid lymph nodes. Examine two incised layers of both masseter muscles. Examine and palpate tongue. *Viscera:* Examine abdominal viscera and mesenteric lymph nodes. Examine and palpate rumenoreticular junction. Examine esophagus and spleen. Incise and examine anterior, middle, and posterior mediastinal lymph nodes and right and left bronchial lymph nodes. Examine and palpate costal and ventral surfaces of the lungs. Incise heart from base to apex through interventricular septum, and examine and cut inner and outer surfaces. Incise and examine hepatic lymph nodes. Incise bile duct in both directions and examine contents. Examine and palpate dorsal and ventral surfaces and renal impression of liver. *Carcass:* Examine internal and external surfaces. Palpate internal iliac and superficial inguinal or supramammary lymph nodes. Examine and palpate diaphragm and kidneys.

Calves and Veal: *Head:* Incise and examine suprathyroid lymph nodes. *Viscera:* Examine and palpate bronchial and mediastinal lymph nodes, heart, and lungs. Examine spleen. Examine and palpate dorsal and ventral surfaces of the liver, and palpate hepatic lymph nodes. Examine abdominal viscera. *Carcass:* Examine exposed inner and outer surfaces. Palpate the kidneys and internal iliac lymph nodes.

Sheep and Goats: *Head and Carcass:* Examine body cavities and outer surfaces. Palpate back and sides of carcass. Examine head, neck, and shoulders. Palpate prescapular lymph nodes. Examine and palpate kidneys. Palpate femoral, popliteal, and superficial inguinal or supramammary lymph nodes. Incise lymph nodes when necessary to exclude caseous lymphadenitis. *Viscera:* Examine abdominal viscera, esophagus, mesenteric lymph nodes, omental fat, and spleen. Examine bile duct and gallbladder and their contents. Examine and palpate liver and costal and ventral surfaces of lungs. Palpate bronchial and mediastinal lymph nodes. Examine and palpate heart.

Pigs: *Head:* Examine head and cervical muscles. Incise mandibular lymph nodes. *Viscera:* Examine and palpate mesenteric lymph nodes and spleen. Palpate portal lymph nodes. Examine dorsal and ventral surfaces of the liver. Palpate left and right bronchial and mediastinal lymph nodes. Examine and palpate dorsal and ventral surfaces of the lungs. Examine and palpate heart. *Carcass:* Examine external and internal surfaces and incise any suspected abnormalities. Examine and palpate kidneys.

Poultry: Examine external surfaces for dressing defects, bruises, and disease lesions. Palpate tibias for bone diseases. Examine internal surfaces, kidneys, and lungs in place. Examine viscera and palpate heart, liver, and spleen.

Horses: *Head:* Examine surfaces. Palpate, incise, and examine mandibular, pharyngeal, and parotid lymph nodes; guttural pouches; and tongue. *Viscera:* Examine and palpate lungs and bronchial and mediastinal lymph nodes, and incise any suspected abnormalities. Examine and palpate spleen, liver, and portal lymph nodes. Incise hepatic duct. Examine remaining viscera. *Carcass:* Examine internal and external surfaces. Palpate superficial inguinal or supramammary and internal iliac lymph nodes. Examine and palpate kidneys and diaphragm. Examine and incise the internal abdominal walls for possible parasitic cysts. Examine spinous processes of thoracic vertebrae, supraspinous bursa, and first two cervical vertebrae for fistulous conditions. Examine axillary and subscapular tissues of white and gray horses for melanosis.

GENERAL CONDEMNATIONS

Livestock clearly showing at premortem inspection any irreversible disease or condition that justifies condemnation as unfit for use as food should be humanely destroyed and disposed of (see p 1639).

Carcasses contaminated by physical, infectious, or toxic agents should not be approved for use as food. Carcasses with generalized conditions or diseases, including cancers, that have so altered the normal characteristics of the meat as to cause it to be inedible or sufficiently abnormal to be reasonably considered unfit for food should not be approved. Localized conditions that do not affect the wholesomeness of the entire carcass should be removed by trimming so that the remainder of the carcass can be used for food.

Special Considerations for Tuberculosis

Tuberculosis: The entire carcass should be condemned when there is evidence of tuberculosis. This includes when an active lesion is present; the animal is cachectic; a lesion is present in muscle, intermuscular tissue, bone, joint, abdominal organs other than the GI tract, or in a lymph node associated with these parts; extensive lesions are present in the thoracic or abdominal cavity; lesions are multiple, acute, and actively progressive; and the nature or extent of lesions does not indicate localization.

An organ or part should be condemned when it or its corresponding lymph nodes contain lesions. When lesions in pigs are localized and are found at only one primary site of infection, such as the cervical lymph nodes, the unaffected parts are acceptable for food after condemnation of the affected organ or part. Even though certain carcasses minimally affected with tuberculosis may be considered safe after commercial cooking, this procedure is not recommended for carcasses that are not inspected in facilities inspected by federal or state officials.

DETECTION OF UNWHOLESOME MEAT

Meat for human consumption should be prepared from animals that were healthy and have been exsanguinated. Animals having physical, infectious, or toxic agents that may be hazardous to human health or that are otherwise unwholesome in their tissues should not be used for food. Fitness for food can be determined by a comprehensive evaluation that may include chemical, histologic, microbiologic, organoleptic, and toxicologic examinations.

Meat should be examined under light of adequate intensity. Foreign objects on the surface or visible within the tissue should be collected for further examination. Items such as feathers, fibers, hair, insect larvae, or parasites may provide valuable data on the species, origin, and handling of the meat. Color, odor, and texture should be noted. Meat should be firm, and cut surfaces should be glossy. Gray or green discoloration may indicate bacterial action. Dark red meat may result from postmortem retention of blood in animals that were not exsanguinated. A stable, bright red color may indicate the unwholesome addition of sulfite. Ultraviolet light may be used to visualize rodent urine and fluorescent substances produced by certain spoilage bacteria. Areas of

bruising, hemorrhage, or inflammation should be readily recognized. Odors from contaminating chemicals, fish, urine, or other sources are unacceptable. When there is uncertainty about odors, a possible unwholesome odor can be enhanced by boiling or frying the meat.

Histologic examination may be used to evaluate abnormalities caused by physical, infectious, or toxic agents. Similarly, microbiologic examination may be used to evaluate spoilage and determine the presence of infectious organisms capable of causing illness in consumers. Chemical and toxicologic examinations should be done when the presence of adulterative or toxic substances is suspected. It may be necessary to increase random microbial testing of meat products to ensure their freedom from bacterial contamination.

ABATTOIR SANITATION

Abattoir buildings, equipment, personnel, and operating procedures should assure the continued wholesomeness and freedom from adulteration of carcasses and meat. Floors, walls, and ceilings should be constructed of materials and in a manner that allows sanitary operation and thorough cleaning. An ample supply of hot and cold water and cleaning materials should be conveniently available for slaughtering, cleaning, and personal hygiene. Water of at least 180°F (82°C) should be available to sanitize equipment and tools after cleaning. Equipment, knives, and utensils that have contacted diseased carcasses should be cleaned and sterilized before being used again. Waste-water drainage, with proper trapping and sewage disposal, should be adequate to maintain the abattoir in a sanitary condition. Ventilation should be sufficient to assure that edible product areas are free of noxious odors. Access of flies, rodents, and other vermin should be prevented. Lighting should be maintained at an intensity adequate for cleaning and inspection. Equipment should be of such material and so constructed as to be readily and thoroughly cleaned and should be properly maintained. Separate, clean containers for edible and inedible materials should be provided at convenient locations. Racks or tables should be provided for heads. Personnel should wear clean garments and follow all hygiene and sanitation procedures.

PREPURCHASE EXAMINATION OF HORSES

See also THE LAMENESS EXAMINATION, p 1097.

Prepurchase examinations are often requested by a potential buyer of a horse. The objective is to reduce the buyer's risks in relationship to the general health and athletic soundness of the horse for sale. The examination is not meant to guarantee soundness of the horse but is an attempt, on the part of the examining veterinarian, to ascertain any preexisting problem or any potential problem that may affect future soundness (eg, degenerative joint disease).

The examining veterinarian should have experience with the specific breed and discipline, as well as knowledge of the purpose and level of exercise for which the horse is being purchased. Ideally, the examiner should also be aware of any related organizational regulations that may influence the prepurchase examination. All notes generated during the examination should be kept in the buyer's file, and a report should be generated for the buyer. The examination should be conducted in a thorough and organized manner, because prepurchase examinations are a common cause of litigation from dissatisfied buyers. The major problems related to litigation are lack of understanding of the prepurchase examination process and the client's unrealistic expectation of a secure investment.

Pre-examination Issues: At the onset, the roles of all involved parties (eg, buyer, trainer, legal agent) in the purchase of the particular horse should be defined. Trainers may or may not have legal agent status. The trainer does have the potential to be responsible for assessing the buyer's expectations for the horse's athletic future and also whether the horse is suitable for the buyer. If an agent is representing the buyer, the examining veterinarian should encourage all information gathered to be communicated to the buyer, along with the report. Buyers of horses have different levels of experience and practical expectations. The veterinarian should ascertain the particular buyer's expectations and define the limitations of the examination, emphasizing that the examination does not eliminate risks.

The buyer is the owner of the information but needs to maintain a level of confidentiality so that the reputation of the horse is not potentially altered because of inappropriate dissemination of medical information.

Through requests by the buyer or the buyer's agent, the seller and/or the seller's veterinarian may agree to provide the horse's medical history to the examining veterinarian. These medical records are returned at the end of the examination. The potential examination and its procedures should be thoroughly reviewed with the buyer and seller verbally and with written explanatory documents. Written release forms for riding the horse, payment, and the seller's permission for any interventional procedures, such as sedation for radiographs, shoe removal, hair clipping, etc, should be obtained before the examination. Partial examinations should not be encouraged. Trial periods are often acceptable and encouraged, especially if the seller can be assured of the horse's safety. One option is to house the horse in a mutually known, professionally managed barn. The seller may request that the horse be insured.

Traditionally, it is recommended that the examining veterinarian have had no contact with the horse or seller in a previous medical or personal role. However, this is often not possible when the horse is being sold within a small community or within the same boarding barn. In such situations, the relationship of the veterinarian to all parties involved should be clearly stated. The opposite situation can occur when the horse is being purchased out of town and the examining veterinarian is not the routine veterinarian for the buyer. The examining veterinarian may want to have the buyer's routine veterinarian review the examination report and any ancillary information, such as radiographs, laboratory tests, etc. Also, if any particular question arises during the examination, an opinion from a board-certified veterinary specialist might be indicated.

If the veterinarian has working knowledge of competition rules related to the discipline in which the horse is being purchased (eg, height requirements), he or she should explain how these rules may apply to the prepurchase examination. The veterinarian should counsel the buyer to learn the specific rules and verify "cards" that belong to the pony or horse. Having the buyer verify any rule requirements may help reduce future problems.

State and international disease testing and other requirements should be reviewed with the buyer and complied with by the examining veterinarian. Drug testing should

be offered to the buyer and its limitations discussed. If the horse is purchased at a competition, or the seller is not known to the buyer, drug testing should be strongly recommended. Even when a buyer does not wish to have drug testing, examiners often collect blood at the time of the examination and store the serum or plasma frozen. It would then be available if any questions arose after the purchase.

Prepurchase examinations of performance horses often are conducted under several different conditions of training. The ideal situation is that the horse is currently active in the particular level of competition for which it is being purchased. However, prepurchase examinations can involve some inherent predictability, even though they are not classically meant for prediction of a horse's health. The following are examples of conditions an examiner may face. Any of these or other modifying conditions should be included in the examination notes: 1) A horse is currently in early training for a specific athletic endeavor and the buyer is ultimately looking to have the horse compete at a higher level. 2) A horse is coming off a lay-off period and has been back in work for only a brief period of time. 3) An older horse that has some infirmities and is being purchased as a schoolmaster by a less experienced rider, in which case the physical demands will potentially decrease with the new buyer. 4) A horse is being purchased for a financial investment. 5) A horse is being purchased as a pleasure or trail horse for a moderate or light workload but the horse's attitude is extremely important. In each of these conditions, different approaches are needed, and different questions should be asked and understood by the examiner.

Examinations of pretraining and brood stock present different issues to the examining veterinarian. The examiner must be alert to potential limiting conditions of the suckling, weanling, or yearling that would diminish its ability to perform its potential future work. In examining mares and stallions, experience with reproductive examination procedures is needed. (See *also* BREEDING SOUNDNESS EXAMINATION OF THE MARE, p 2189, and BREEDING SOUNDNESS EXAMINATION OF THE MALE, p 2230.) In all situations, thorough knowledge of the rules of the specific breed and any governmental disease regulations is critical.

History: The simplest way for the veterinarian to accumulate history before the examination is to have the seller complete and sign a history form. This helps to legally bind the seller in the transaction and gives

information that may or may not have been known to the buyer, his or her agent, or the examining veterinarian. A similar questionnaire can be devised for the buyer as to his or her expectations, potential use, and previous experience with the horse in question. Examples of such forms are readily available on the Internet and may be modified as needed.

Physical Examination: The examination for a performing horse can be divided into four sections. The first part is observing the horse in the stall. The second includes observing the horse on a lead strap at a walk and a trot on a straight line, doing flexion tests, and in a circle with a long line. The third part of the examination involves observation of the horse while it is being ridden. The fourth part includes diagnostic procedures such as radiography and ultrasound.

In the UK, there is a standardized 5-stage vetting procedure: Stage 1, preliminary examination; Stage 2, trotting up in hand; Stage 3, strenuous exercise ridden or longed to evaluate conditioning, heart, breathing, and strains that might be expressed; Stage 4, a period of rest for as long as 30 min to evaluate heart and lung recovery, during which time paperwork such as identification can be completed; and Stage 5, a second trot in hand and foot evaluation.

Phase 1: The key to any successful prepurchase examination is having a systematic, consistent routine. At some point during the first part of the examination, a thorough identification of the horse should be recorded. This can be a written description of its color and age verification with inspection of the teeth. Digital photographs are easily adapted and helpful in prepurchase identification. Notations of markings and any other permanent peculiarities to the horse's body are also beneficial. The most common markings include a star, stripe, blaze, or snip on the face of the horse. Any white markings on the legs should also be described. Other markings that are valuable to record include whorls on the face and neck, brands, and tattoos. The presence of any scars, splints, or joint effusion should be noted. In some cases, brands or tattoos can give information, such as age (eg, American Jockey Club tattoos have an alphabet letter before the number; "A" represents the years 1971 and 1997, "B" 1998). The date, time, and place of the examination should also be recorded. The initial part of the examination ideally should be done in a stall or area out of direct sunlight, dark enough for an

ophthalmologic examination. Temperature and pulse recordings, auscultation of the heart and lungs, and oral examinations can be done in the quiet and controlled confines of the stall. It is also worth looking in the stall for wood chewing, the character of the manure and feed, and/or oral medication remaining in the feed bucket.

Phase 2: The second phase of the examination outside the stall can begin with general body and skin condition. The body condition score (1–9) can be assigned a number from thinness (1) to obesity (9). Scores of 4, 5, or 6 are considered normal. Each of the front and hind feet should be thoroughly examined; mismatching, abnormal foot conformations, flares, dishing, type of shoeing, and rings should be noted. Photographs that document body condition scoring and feet can be part of the examination and may simplify a written description. Next, visual observation and palpation of the limbs, hoof examination (including hoof testers), passive and active flexion tests, and watching the horse move on different surfaces on a straight line and in a circle should be done. It is also valuable to perform a basic neurologic examination.

Phase 3: Many examiners feel it is helpful to watch the horse being ridden to exclude any subtle unsoundness. It also gives the examiner some observations and insight into the potential of the rider, if it is the buyer. These observations are worth noting, even though it is the trainer's and buyer's responsibility to determine the suitability of the horse. It is in this portion of the examination that the British Equine Veterinary Association recommends exerting the animal at a level appropriate for its age and fitness. Having the horse hand gallop for 5–10 min so the examiner can evaluate breath sounds and perform cardiac auscultation is recommended. Young or untrained horses

can be longed. The horse is then monitored during recovery. Next, the jogging in hand is repeated so that any subtle lameness that might have been accentuated during the exercise stage can be detected. All observations are duly recorded in the report.

Phase 4: The fourth part of the examination should include any diagnostic procedures necessary to determine soundness, including radiographs (particularly of the feet, hocks, and stifles), ultrasonography, and nuclear scans. (See also THE LAMENESS EXAMINATION, p 1097.) Radiography is the most common diagnostic procedure performed. A recent retrospective analysis of radiography in equine prepurchase examinations suggests that higher radiographic grades (eg, 2–3) in the navicular bone and distal phalanx are associated with lameness, whereas similar grades in the tarsus were less likely to be associated with lameness.

Report of Findings: A summary report should be prepared and provided to the buyer. There are many published samples of these reports, available in letter or check-off list form. The report should describe any abnormal or undesirable findings and include an opinion as to the functional effect of these findings. Tests that were recommended to but declined by the buyer should be noted in the final report. The American Association of Equine Practitioners publishes guidelines for reproduction, medications, sale issues such as cryptorchidism, dental malocclusions, postsale examination of the upper respiratory tract of horses intended for racing, radiograph custody, and sale disclosure. Specific guidelines to report prepurchase examinations are also included. The British Equine Veterinary Association also publishes guidelines to conduct a prepurchase examination.

PREPURCHASE EXAMINATION OF RUMINANTS AND SWINE

See also BIOSECURITY, p 2068.

The buying and selling of cattle, sheep, goats, cervids, and swine are critical to the continuing vitality of the global livestock industry, and the health of animals to be

sold or moved to other premises is extremely important. The purchaser, the seller, state and federal animal health officials, and others engaged in livestock transactions want assurance that the

animals are healthy and will not introduce disease into the new herd or area.

Within the USA, every state has specific animal health requirements that must be satisfied to legally move an animal into the state. Because these requirements frequently change in response to a state's efforts to protect their animal populations, it is always recommended that the Office of the State Veterinarian in the destination state be contacted before a move. Animals that arrive in a state without the proper health certification will likely be quarantined until the proper tests and inspections can be accomplished. In some rare instances, the animals may be destroyed because of the risk they pose to the state's animal populations.

The state of destination may require additional statements about the animals in the shipment. These statements, which generally provide additional information about the animals and their origin, are added to the body of the certificate of veterinary inspection (CVI). A permit number may also be required for some species. Collectively, these additional documents provide assurances that the animals meet or exceed the requirements of the state.

Because of continuing progress in eradication programs for brucellosis, tuberculosis, and pseudorabies in the USA, many states have been declared free of these diseases by the USDA. Once a state is designated as "free," other states may waive the requirement for an individual animal test for these diseases and will instead receive the animals based on the state of origin's status. If a herd or flock has been declared free of a disease, including classification as accredited-free, certified-free, or qualified-free, many states will waive an individual animal test for the specific disease.

Electronic CVI, especially when coupled with radiofrequency identification (RFID) devices used as official identification, reduce the time necessary to prepare and distribute the required paperwork. Although RFID devices are not currently required for interstate movement of animals, a recognized form of official identification for each animal is required. If a state has specific identification requirements, they can be determined when contact is made with the state of destination's animal health official.

Countries also have specific health regulations for imported animals. These regulations have been developed to protect their animal populations for many of the same reasons individual states have

established specific importation requirements in the USA. Global standards for the movement of animals and animal products are developed by the OIE.

The chief veterinary official (CVO) for each country is responsible for protecting the health of the animal populations in that country, as well as the public health in the case of zoonotic diseases. Animal health requirements for the destination country can be obtained by contacting the CVO of that country or more simply by contacting the office of the USDA Area Veterinarian in Charge (AVIC) located in nearly every state. The AVIC has access to the animal health requirements for all foreign destinations. Most of the CVI prepared for animals being shipped to a foreign country must bear the endorsement of the AVIC before the animals leave the state of origin. Animals that are not accompanied by the proper documentation will be detained or refused at the border or point of debarkation.

It is not unusual for an exhibition, sale, or private treaty agreement to have requirements for animal movement that exceed those of the state or country of destination. To determine these unique requirements, the host of the event or the buyer of the animal should be contacted.

The USDA veterinary accreditation program facilitates the movement of animals by enlisting private veterinary practitioners. This system has reduced the need for state and federal animal health agencies to provide these essential services to livestock producers. The accredited veterinarian is ultimately responsible for the completeness of any document prepared and for certifying that the animals have been inspected and are not showing signs of infectious, contagious, or communicable diseases.

In the examination of any animal before sale, several points should be emphasized:

- 1) The veterinarian is working for the person paying the fee and reports only to that person. The person responsible for compensating the veterinarian should be informed of the cost before the inspection.
- 2) The purpose for which the animal is to be used should be clearly established before the examination.
- 3) The examining veterinarian must be knowledgeable not only in the care and treatment of animals but also aware of the purpose for which they will be used.

Because legal action against the examining veterinarian is a possibility, a veterinarian may choose not to provide a written report for prepurchase examinations. However, a written record of findings should be made, because it may be needed

at a future date. The responsibility of the veterinarian is to supply information and identify abnormalities; the prospective purchaser must make the decision whether to purchase. The prospective purchaser may also select a second veterinarian to perform an additional inspection.

The examination is divided into three parts: history, clinical examination, and special examinations or diagnostic procedures.

History: A complete history should be obtained by questioning the seller, examining the seller's records, and observing the remainder of the herd or flock and the management conditions. The animal's breed, sex, age, color, markings, tattoos, ear tags, brands, and other identification aids should be noted. If applicable, registration papers should be checked and the animal's identity definitively established.

For a breeding animal, the records of its sire and dam also should be considered, including their breeding ability, the possibility of heritable defects in the line to which each belongs, and, if dead, the cause of death. Also, breeding records of the animal itself should be reviewed to determine its fertility. Breeding records of the herd of origin of the animal should be examined for evidence of disorders that may affect reproduction. If the animal is an adult female, the breeding dates and stage of pregnancy, if applicable, should be noted.

Records should be examined to determine whether the animal has had any previous diseases, injuries (and their severity), or surgical procedures. Previous vaccinations, their type, and date of

administration should be noted. The health of the herd or flock of origin and possible contacts with other animals before the sale should be determined, because animals so exposed could be in the incubation period of disease. It should also be established whether the animal received any drugs or medication that could alter its normal state. If this cannot be established in the history, it may be prudent to perform assays for suspected medication.

Clinical Examination, Special Examinations, and Diagnostic Tests: All areas of the body and their functions should be examined. The clinical examination should establish the current state of the animal's health and condition of each body system.

As previously discussed, some diagnostic tests are performed at the time of sale to satisfy the requirements of the state or country of destination, but additional diagnostic tests and special examinations may be required by the seller, buyer, or others involved in the transaction. It may also be necessary to conduct additional testing as indicated by the findings of the clinical examination. When certain diseases are not present in the seller's geographic area but are endemic in the purchaser's area, vaccination (if available) for those specific diseases is frequently required before movement. The CVI prepared after the examination must accurately reflect the findings of the accredited veterinarian.

If a male is to be purchased for breeding purposes, a complete breeding soundness examination (see p 2230) should be conducted.

RADIATION THERAPY

Radiation therapy has seen dramatic increases in demand and sophistication in recent years, which has led to creation of a board specialty in radiation oncology, granted by the American College of Veterinary Radiology. The sophistication and scope of both veterinary imaging and radiation therapy has advanced to the point that only a few radiologists now actively practice in both the fields of imaging and therapy.

Historically, radiation therapy was delivered using orthovoltage x-ray machines or very large activities of 64-cobalt and 137-cesium. Except for a few specialized instances, orthovoltage x-ray machines have fallen from favor because of the intensity of adverse radiation reactions associated with their use and their limited flexibility. Cobalt and cesium are no longer used because as long-lived isotopes they are extremely dangerous and

TABLE 4 SELECTED COMMON NEOPLASMS THAT CAN BE TREATED WITH RADIATION THERAPY

Tumor Type	Radiosensitivity	Comments
Nasal adenocarcinoma	Intermediate	Usually respond well but often recur
Nasal squamous cell carcinoma	Low	Response is often minimal
Nasal chondrosarcoma	Intermediate to high	Some subtypes respond better than others
Nasal osteosarcoma	Low	Response may be better if after surgery
Oral melanoma	Low to intermediate	Poor response usually unless after surgery
Oral squamous cell carcinoma	Low	Especially poor in cats; aggressive treatment required
Osteosarcoma	Low	Metastatic disease in >90%; pain palliation
Chondrosarcoma	Intermediate	Best when small; metastasis a problem
Fibrosarcoma	Low to intermediate	Depends on tissue of origin
Injection-related fibrosarcoma	Low to intermediate	Best if done after first surgery, poor later
Thyroid carcinoma	Intermediate to high	Usually respond very well; ¹³¹ I possible
Thyroid adenoma	High	Treat with ¹³¹ I (>95% cure)
Salivary adenocarcinoma	Intermediate	Usually respond well, especially in cats
Brain tumor – meningioma	Intermediate to high	Usually stabilizes mass; good clinical result
Brain tumor – glioma	Low to intermediate	Depends on size, location, and clinical signs
Brain tumor – lymphoma	High	Most effective treatment for CNS lymphoma
Brain tumor – metastasis	Intermediate	Effective but short term due to other disease
Spinal cord mesenchymal tumor	Intermediate	Reasonable response but dose limited by cord
Spinal neurofibrosarcoma	Low to intermediate	Short-term response good but commonly recur
Lymphosarcoma	High	Excellent response but can only treat locally
Cutaneous lymphoma	High	Often curative
Nasal lymphoma	High	Good response, often very durable
Thymoma	Low to high	Low for scirious form, high for lymphocytic

(continued)

TABLE 4

SELECTED COMMON NEOPLASMS THAT CAN BE TREATED WITH RADIATION THERAPY *(continued)*

Tumor Type	Radiosensitivity	Comments
Mediastinal chemo-dectoma	Low	Large masses, dose limited by heart and lungs
Adrenal neoplasias	Low	Difficult to accurately localize treatment
Transitional cell carcinoma	Intermediate	May respond well initially but recur
Prostatic adenocarcinoma	Low to intermediate	Data available on response is quite variable
Mast cell tumors	Intermediate to high	Very good for low grade, less for high grade
Peripheral nerve sheath tumor	Intermediate to high	Strongly recommended after surgery
Soft-tissue sarcoma	Low to high	Improves control after surgery, not alone
Lick granuloma	Intermediate to high	Treatment of last resort, often works well
Transmissible venereal tumor	High	Very good control even for large tumors
Equine sarcoid	High	Used in refractory tumors, brachytherapy
Equine nasal carcinoma	Intermediate to high	Beam treatment effective, very few sites
Equine ocular squamous cell carcinoma	Intermediate to high	Best treatment when bone involved

heavily regulated in most of the world. Today, it is virtually impossible to purchase these sources because of public safety concerns.

Veterinary radiation therapy practices today almost exclusively use linear accelerators as the source of the ionizing radiation used to treat neoplasia and occasionally specific benign diseases. These machines produce powerful x-rays and electron beams with energies of 4–20 million electron volts. The x-rays are used to treat deep-seated tumors, whereas electron beams are generally used to treat tumors of the skin and subcutis. Linear accelerators are complex machines that require the support of a medical physicist to maintain safe and effective use. This increased support load is offset by the machine's flexibility and speed, which is necessary as treatment techniques become more sophisticated and complex.

Computerized treatment planning systems are now used by veterinary radiation oncologists to improve the

localization and distribution of the therapeutic beam within the patient. This reduces the dose to healthy tissues relative to the dose to the neoplastic tissue being treated, increasing cure or control rates and reducing the severity of healthy tissue complications. These programs are best used in conjunction with CT or MRI images, which determine the position and extent of the tumor within the body and its relative position to healthy structures. Many hours of work may be required to generate a treatment plan for a large, complex tumor.

Patients are then treated in precisely the same position as they were in for the CT or MRI. Repeatability of positioning is of paramount importance and can be achieved by using special positioning devices in conjunction with careful landmarking. Proper patient positioning is then confirmed using an imaging system integrated with the linear accelerator. Once proper positioning is confirmed, the treatment can be administered. Great attention to detail is necessary during this part of the treatment,

because even small changes in position can have profound effects on the distribution of the radiation dose delivered. This is especially true in CNS tumors, in which the lesion diameter may be only 1 cm.

Except in rare instances, all radiation therapy treatments using external sources of radiation must be delivered with the patient immobilized by general anesthesia. Because the plane of anesthesia required is light and the procedures are typically of a relatively short duration, this repeated anesthesia is well tolerated, and complications are few with proper observation and monitoring. This requirement for anesthesia is rarely if ever a contraindication for implementing a course of radiation therapy.

A typical course of radiation therapy consists of multiple doses of radiation delivered on different days. This is done to allow healthy tissues to heal somewhat between doses. Healthy tissues have a greater ability to repair radiation damage than neoplastic tissues; therefore, use of multiple small doses of radiation, although it has a cumulative effect, favors survival of healthy over neoplastic tissues. Most radiation therapy regimens designed with curative intent use 15–20 individual doses (fractions) of radiation. Each dose of radiation may be delivered using several different fractions of radiation of differing size, shape, and intensity. In cases when the tumor is too advanced to be controlled by radiation, palliative therapy using larger doses and fewer fractions of radiation may be used to retard the tumor's growth or reduce associated pain. Such a palliative approach may also be used when mandated by owner finances.

Whenever possible, removal of a tumor by surgery is preferred. However, in many instances, large neoplasms, or those in critical areas such as the brain, are not amenable to complete or even partial surgical removal. Even when a tumor is grossly removed, microscopic foci of neoplastic cells often extend beyond the limits of the surgical field. This is more common for some tumor types than for others. In all of these instances, radiation therapy, often in combination with chemotherapy, is useful in treating the remaining cancer. Radiation therapy is often the treatment of choice for brain tumors, nasal tumors, and other neoplasms of the head and neck in which even partial resection may be extremely disfiguring or carry a high risk of mortality. It may be the only treatment option for cancer of the vertebral column and pelvic canal. Radiotherapy is also used to treat tumors in

the mediastinum and soft tissues of the skin and subcutis either before or after surgery. It is seldom used in the treatment of lung neoplasia or in the treatment of neoplastic disease of the abdominal cavity because of the mobility of tumors in these areas. However, treatment of mediastinal tumors and those of the pelvic canal, such as thymoma and prostatic carcinoma, are possible and may well be indicated. As the sophistication of radiotherapy techniques increases, more and more types of neoplasia are being treated at least in part by radiation therapy.

In many instances, radiation therapy, especially when combined with surgery and chemotherapy, may be curative. However, radiation therapy can delay the development of disease or control its expansion in many instances. Radiation oncologists typically talk in terms of control rate rather than cure. Sometimes, the control may be relatively short lived, and recrudescence of the tumor occurs within months after completion of the treatment regimen. In other cases, control may last several years or even until other disease processes supersede the neoplastic disease. Unfortunately, it is seldom possible to predict even within an individual tumor type which patients will experience good control and which ones will not. Continual advances in the evaluation of genetic markers within tumors hold the promise of being able to predict this in the future.

Because of the risk of serious and potentially life-threatening complications associated with this treatment modality, the complexity of the equipment and sophistication of the radiation therapy procedures should only be prescribed by and administered under the supervision of a veterinarian with special training, experience, and certification in the field of veterinary radiation oncology. A veterinary radiation oncologist should also be consulted any time further treatment is contemplated for neoplasia that has been treated by radiation therapy. This is particularly important if surgery within the radiation field is being considered.

Brachytherapy is the implantation of radioactive sources into the tumor to achieve radiation therapy. It is seldom used for treatment of cancers in animals because of the difficulties associated with maintenance of the sources and keeping the sources in place within the tumor. The notable exception to this is the use of radioiodine to treat thyroid adenomas in cats and adenocarcinomas in dogs. Radioisotopes developed for treatment of

metastatic osseous neoplasia in people are also useful in the treatment of primary and metastatic bone cancer in dogs and cats. Such "nuclear oncology" treatments are being continually developed for use in human medicine and are directly applicable to veterinary patients as well. In fact, these treatments are typically developed in veterinary patients before being introduced into human medicine.

Implantable radiation sources that are so small (microns or even nanometers) that they are permanently implanted within the body blur the margins between radiation therapy and nuclear medicine. The implantation of such sources comes under the heading **interventional radiology**. Interventional radiology procedures such as catheter placement and CT guidance of source implantation are used to introduce both macroscopic and microscopic scale brachytherapy sources into neoplasms located deep within the body. Targeting of such agents is accomplished either by using sources of sufficient size to be locally retained within the tissue or capillaries of the tumor or by targeting them specifically to tumor cells using monoclonal antibody labeling. These techniques have been around for many years but have not

received widespread attention in veterinary medicine because of the cost of both the agents and the equipment required for their implantation. However, in recent years there has been a marked upswing in the interest in such interventional radiology procedures for both treatment and diagnosis, not only of cancer but also of many other conditions. Such techniques may well increase the interest in and availability of brachytherapy procedures. Because of the risk of excessive radiation exposure and contamination of the patient or hospital, these procedures should be performed only by veterinarians with appropriate training, experience, and support in a properly licensed facility.

A full list of appropriately trained and accredited veterinarians as well as a list of radiation therapy facilities can be obtained through the American College of Veterinary Radiology or the American Veterinary Medical Association.

The radiosensitivity of virtually any neoplasm is higher in minimal or microscopic disease. Some neoplasms respond well initially but tend to recur at some time after radiation therapy. The time to recrudescence is highly variable between and within tumor types.

EMERGENCY MEDICINE INTRODUCTION

Emergency patients present special challenges because their underlying disease processes can cause immediate, life-threatening problems that require rapid and aggressive intervention. In addition, the full extent of the animal's illness, injuries, or toxicity may not be evident for 24–48 hr or more after initial presentation.

Problems can arise from an acute illness, toxicity, or injury; from a chronic illness that has decompensated; or from an unexpected complication of a concurrent illness. The status of all postoperative patients should be considered critical until life-threatening anesthetic or surgical complications are excluded. The golden

rule of emergency medicine is to treat the most life-threatening problems first.

Variables that contribute to the overall success of emergency treatment include the severity of the primary illness or injury, the amount of fluid or blood lost, age of the animal, previous health problems, the number and extent of associated conditions, time delay in instituting therapy, the volume and rate of fluid administration, and the choice of fluids (eg, crystalloid, blood components, or synthetic colloids). Therapy must be done at the right time, in the right amount, and in the right order. Therapeutic failures are generally a result of failing to act expeditiously at a crucial moment.

Emergency care often begins with the owner's initial telephone call. Instructing the owner on first aid and transport procedures can be life-saving for the animal. The clinic and staff must be in readiness, especially if more than one animal in critical condition arrives at the same time. The primary survey, or **triage** (see below), requires a quick and accurate assessment and decision regarding the stability of the animal. As life-threatening airway, breathing, and circulation problems are identified, immediate treatment is initiated. Once the animal has been stabilized, a more systematic and organized approach to the history and physical examination (secondary survey) and more specific diagnostic and therapeutic procedures aimed at the underlying cause can be done.

FIRST AID AND TRANSPORT

Owners can provide significant medical assistance at the scene of the injury. At the time of the initial telephone call, the owner should be questioned about the level of consciousness, breathing pattern, type of injury or toxicity, and even some aspects of the animal's perfusion (eg, gum color, level of responsiveness, heart rate). The first concern is for the safety of the owner. Placing a light cloth over the head of the animal can lessen external stimuli that may cause fearful and aggressive reactions. Owners can be instructed as to how to muzzle most dogs using a long strip of fabric if there are no facial injuries or respiratory distress. Cats can be placed in dark boxes to minimize stress during transport; the box should have holes large enough so that the cat can be observed. It is vital that the owner adequately restrain the pet before starting any first aid procedures to ensure the safety of the owner and pet.

When moving the animal, motion of the head, neck, and spine should be minimized. A flat, firm board of wood, cardboard, or

thick fabric can be used to provide support. Radiographs can also be taken through these materials without having to move the animal when it arrives at the hospital.

Rapid detection of cardiopulmonary arrest (CPA) in an unconscious animal can be difficult for owners. The pet's lack of response to external stimuli or presence of limp body tone are unreliable indicators of CPA. Instructing owners to feel for a pulse or heart rate can delay intervention. Instead, owners can be instructed to watch for chest excursions and to touch the cornea or eyelids to elicit a corneal or palpebral reflex in an unconscious pet, with absence of one or both indicative of CPA.

Mouth-to-nose resuscitation and chest compressions (see p 1670) may provide enough respiratory and circulatory support to maintain life during transport. If the animal is cyanotic and collapsed (and was pawing at the face), an upper airway obstruction may be present; the owner should be instructed how to perform a Heimlich maneuver or sudden chest compression to relieve the obstruction and then to manually clear the airway. If the animal is unconscious and not breathing, the owner should be instructed to close the animal's mouth, place their lips over the animal's nostrils, and initially give 3–4 strong breaths. If the animal's breathing does not become spontaneous, the owner should breathe for the animal at a rate of 10 breaths/min. The owners can also be instructed to compress the esophagus behind the mandible on the left side so that most of the air will go down the airway instead of into the stomach. Chest compressions should be initiated at a rate of 100–120/min. A compression:ventilation ratio of 30:2 can be performed. This necessitates another person to drive during transport.

Owners should be asked whether hemorrhage is ongoing or whether bleeding was seen at the site of injury. Pulsating arterial bleeding should be controlled by direct digital pressure and then by a pressure bandage. Any long pieces of fabric or gauze can be used. Often, washcloths and hand towels are adequate when applied with mild pressure. Additional material can be placed over the original bandage if it becomes soaked with blood. If the bleeding from a limb is venous (dark, oozing), the limb can be elevated above the heart. Tourniquets should be used only on appendages (eg, limbs, tail) when compression wraps have failed to control bleeding. The tension on the tourniquet must be relaxed to allow blood flow to the distal limb and then retightened every 5–8 min.

Penetrating foreign objects (eg, sticks, arrows) should be left in place during transport; however, care should be taken to guard against movement of the object to prevent further injury. It is often necessary to stabilize the shaft of the penetrating object just outside the body and, holding it firmly, cut off the shaft, leaving a portion exposed so it can be easily located.

In dogs with fractures below the elbow or stifle with significant displacement—and, therefore, concern for movement causing damage to muscle, nerve, vessels, or bone—support can be provided during transport. Once the pet has been adequately restrained, the owner can make a support splint from a rolled newspaper or magazine, which is secured in place by long pieces of fabric or duct tape.

Animals with altered mentation after trauma should be transported with the head level with the body or elevated 20°. There should not be any jerking or thrashing motions, and manipulations of the neck or occlusion of the jugular veins should be minimized.

If a toxic ingestion is present, the owner should be instructed to bring the animal immediately to a veterinarian. Instructing an owner by phone to administer hydrogen peroxide or other substances carries the risk of further injury such as a vagal response (resulting in collapse and bradycardia), choking on vomitus, aspiration pneumonia, further toxic injury from caustic substances, or mucosal injury from hydrogen peroxide administration. If possible, the container of the likely toxin should be brought in.

READY AREA

A central area of the clinic should be designated as the “ready area,” where resuscitation therapeutics and equipment are organized and available for immediate use. Front desk and triage staff should be aware of presenting conditions that require immediate evaluation by a veterinarian. All members of the veterinary team must be familiar with the ready area and location of all necessary emergency equipment and medications. Regular drills should be organized for emergency situations such as CPA with subsequent cardiopulmonary resuscitation efforts to ensure everyone knows his or her role and to improve techniques. An emergency treatment or “crash” cart should contain endotracheal tubes of various sizes, a laryngoscope, syringes of different sizes with 18- or 20-gauge needles attached, and drugs for cardiac resuscitation. Oxygen and a small and large bag-valve-mask apparatus or other ready access to oxygen (such as an anesthetic machine flushed free of anesthetic gas) should be immediately available, so positive-pressure ventilation can be started. Other necessary materials include hair clippers, surgical scrub, tape, intravenous and intraosseous catheters with flushing solutions, intravenous isotonic crystalloids, pressure infusion bags, synthetic colloids, bandage material, and trauma transport materials. Additional beneficial equipment includes a defibrillator, monitoring devices (ECG, SpO₂, ET/CO₂, and indirect blood pressure), a suction unit with Yankauer and whistle tip suction attachments, and warming devices.

EVALUATION AND INITIAL TREATMENT OF THE EMERGENCY PATIENT

PRIMARY SURVEY (TRIAGE) AND RESUSCITATION

Triage is the art of assigning priority to emergency patients and their problems based on rapid assessment of historical and physical parameters (see TABLE 1). Several historical or observed problems warrant transfer of the animal to the treatment area regardless of physical findings. These problems include known or suspected trauma, poisonings, profuse

vomiting or diarrhea, urethral obstruction, labored breathing, cardiopulmonary arrest, seizures, loss of consciousness, severe alterations in mental state, acute inability to walk, excessive bleeding, prolapsed organs, potential snake bite, heat prostration, open wounds exposing extensive soft tissue or bone, anemia, burns, dystocia, shock, and disease that may rapidly decompensate such as gastric dilatation and volvulus and allergic reactions.

TABLE 1 PARAMETERS TO EVALUATE DURING TRIAGE

Parameter	Evaluation	Significance
Mucous membrane color	Pink	Normal PCV and adequate perfusion
	Pale or white	Anemia or shock
	Cyanotic	Severe hypoxemia
	Yellow	Increased serum bilirubin due to hepatic disease or hemolysis
Capillary refill time	1–2 sec	Normal perfusion and rapidity with which capillaries refill with blood
	>2 sec	Poor perfusion or peripheral vasoconstriction
	<1 sec	Hyperdynamic states; could be associated with fever, heat stroke, distributive shock, or early compensatory stage of hypovolemic shock
Heart rate	70–120 bpm (small dogs) 60–120 bpm (large dogs) 120–200 bpm (cats)	Normal heart rates; indicate that at least one component of cardiac output is normal
	Bradycardia	Decreased cardiac output and subsequent poor perfusion; cats in particular develop bradycardia (<120 bpm) in shock; an irregular, slow heart beat can be associated with imminent cardiac arrest, severe arrhythmias, or metabolic derangements (hyperkalemia, hypocalcemia, etc)
	Tachycardia (dogs >180 bpm, cats >220 bpm)	Compromised diastolic filling; sinus tachycardia often results from hypovolemic shock or pain; tachycardia that is irregular or associated with pulse deficits usually indicates an arrhythmia, and an ECG is indicated
Pulse rate and quality	Strong and synchronous with each heart beat	Normal; both femoral and digital pulses should be palpated
	Irregular	Usually indicative of a cardiac arrhythmia
	Bounding	Hyperdynamic (compensatory) state of shock
	Weak or absent	Decreased cardiac output, peripheral vasoconstriction, decreased pulse pressure, or thromboses
Level of consciousness	Alert and responsive to surroundings	Normal overall neurologic and metabolic state
	Depressed or obtunded (less responsive to visual and tactile stimuli, sleepy appearance but still arousable)	Can be caused by any illness or decreased perfusion; may be mild, moderate, or severe

(continued)

TABLE 1 PARAMETERS TO EVALUATE DURING TRIAGE (continued)

Parameter	Evaluation	Significance
	Stupor (arousable only with painful stimuli)	Severe neurologic or metabolic derangements
	Comatose (unarousable with any stimuli) or seizures (usually associated with whole body convulsions, salivation, facial tremors, possibly involuntary urination and defecation)	Abnormal cerebral electrical activity from primary neurologic disease or secondary to metabolic derangements seen in diseases such as diabetes, hepatic encephalopathy, hypoglycemia, or toxin exposure; accurate history or prior health problems, current medications, and possible toxin exposure important
Level of pain	Vocalization, changes in behavior (avoidance, aggression), or physical changes (tachycardia, dilated pupils, etc)	Clinical signs can be similar to those seen in compensatory stage of shock; pain delays healing and must be treated.

Airway, breathing, and circulation are evaluated sequentially, followed by examination for sources of hemorrhage, and determination of the level of consciousness and level of pain. The most common reasons for an animal in catastrophic distress include 1) airway—airway obstruction or disruption; 2) breathing—cyanosis from tension pneumothorax, alveolar flooding (edema fluid or blood), severe bronchoconstriction with air trapping or brain-stem pathology affecting ventilation; and 3) circulation—shock (decreased perfusion), cardiopulmonary arrest, extreme bradyarrhythmias or tachyarrhythmias, cardiac tamponade, and acute intravascular volume loss usually due to internal or external hemorrhage.

Airway

Life-threatening airway pathology (catastrophic or severe) includes complete large airway obstruction and partial obstruction of the large and small airways.

Diagnosis: Animals with complete large airway obstruction are unconscious and apneic. Partial large airway obstruction causes noisy breathing (stridor or stertor), heard without the aid of a stethoscope. Cyanosis and anxiety are often present with loud referred airway sounds heard throughout the thorax on auscultation. Compromise of the extrathoracic airway (nasal passages, pharynx, larynx, or cervical trachea) causes inspiratory stridor; compromise of the intrathoracic trachea or bronchi causes

expiratory stridor. Stertor is most common with pharyngeal disease. Possible causes of large airway pathology include foreign bodies, edema, laryngeal paralysis or paresis, tracheal collapse, elongated soft palate, aspiration of stomach contents, neoplasia, and pharyngeal hematomas. Animals with severe small airway obstruction have labored breathing with an expiratory push of the diaphragm, cyanosis, and anxiety. Auscultation reveals high-pitched wheezes throughout the lung field. In severe life-threatening situations, the animal is cyanotic, open-mouth breathing, collapsed, and asphyxiating. Common causes include anaphylactic reactions; asthma (cats); and bronchial obstruction from edema, mucus, exudates, or foreign material.

Treatment: Unconscious, apneic animals require immediate tracheal intubation. The clinician should be practiced in orotracheal intubation of animals in dorsal, lateral, and sternal recumbency. If an obstruction is present, it must be immediately relieved (with suction, manual removal, or the Heimlich maneuver) or bypassed via emergency tracheotomy. Once an airway is established, confirmed, and secured, ventilation is initiated with 100% oxygen via a bag-valve-mask. Should auscultation during ventilation detect absent or muffled lung sounds indicative of pleural fluid or air, immediate thoracocentesis is warranted. Heart sounds and pulses are checked and, when absent, cardiopulmonary resuscitation (*see* p 1670) is initiated.

With partial large airway obstruction, flow-by oxygen is delivered through oxygen tubing at a high flow rate aimed at the open, panting mouth until an airway is secured or, if appropriate, a transtracheal or nasotracheal oxygen line is placed. Heavy sedation using a narcotic/tranquilizer (eg, butorphanol 0.2–0.4 mg/kg with or without acepromazine 0.01–0.05 mg/kg) combination may be used to relieve anxiety and struggling, to allow a cursory examination of the pharynx and larynx, and to remove pharyngeal foreign bodies. When tracheal intubation is necessary, general anesthesia should be induced using rapid-acting IV anesthetics such as etomidate (0.5–3 mg/kg), ketamine/diazepam combination (5–20 mg/kg and 0.1–0.4 mg/kg), or propofol (6–8 mg/kg to effect). The ability of the laryngeal cartilages to abduct during inspiration should be assessed during intubation and a full oropharyngeal examination performed when time allows. A tracheotomy is necessary when pharyngeal, laryngeal, or tracheal pathology prevents orotracheal intubation or when prolonged intubation is anticipated. A transtracheal catheter can be used to provide oxygen support during stabilization. When the airway pathology lies within the thoracic cavity, airway patency must be established down to the bifurcation of the trachea. Once the airway is established, it should be secured with a tie and inflation of the cuff mechanism, as well as confirmed with at least two of the following methods: palpation of the tube within trachea in the cervical region, auscultation of the lungs and visualization of chest wall movement when a breath is administered, visualization of the tube entering the airway, placement of an end-tidal CO₂ monitor, or radiographs.

Cyanosis from small airway obstructive disease is treated by providing oxygen by flow-by, hood, or nasal cannula and sedation with a narcotic/tranquilizer combination. Epinephrine is given for its bronchodilatory effects both in anaphylaxis (0.01–0.02 mg/kg, IV) and in life-threatening asthma (0.02 mg/kg, IM). Corticosteroids (prednisone sodium succinate, 15 mg/kg, IV, or dexamethasone, 2–4 mg/kg, IM or IV) are given for allergic bronchitis, asthma, or severe swelling of the larynx or pharyngeal tissues. Other bronchodilators, such as aminophylline or terbutaline, are given IM, or albuterol can be given by nebulization in the case of an animal in crisis.

Breathing

Diagnosis: Compromised breathing in both dogs and cats manifests with an increased

respiratory rate and effort, immediately followed by a change in the respiratory pattern. Postural changes (orthopnea) follow; dogs stand with the elbows abducted and the back arched or high on the rear haunches with the head and neck extended, whereas cats may sit crouched on all four limbs with the sternum slightly elevated. Obvious labored, open-mouth breathing, and changes in mucous membrane color (gray and/or blue [cyanosis]) develop last and indicate significant loss of pulmonary function and impending pulmonary arrest.

The location of the pathology—pleural space or parenchymal disease—can be determined at presentation by careful observation of the breathing pattern and auscultation of the thorax. This will direct resuscitative efforts. Taking radiographs or performing stressful diagnostic procedures before the animal has been stabilized can lead to rapid decompensation.

Pleural space disease causes asynchronous breathing. The chest expands on inspiration as the abdomen is pulled inward, then the chest moves inward on expiration as the abdomen expands. In cats, breathing is slower and more deliberate than in dogs. The respiratory pattern is the same whether air, fluid, or abdominal contents are in the pleural space. Thoracic auscultation reveals muffled lung sounds over the affected regions.

Lung parenchymal disease causes quiet, smooth breathing, with the chest and abdominal wall moving in the same direction. Inspiration and expiration are equally labored unless concurrent small airway edema or constriction adds an expiratory push. Cats demonstrate rapid, shallow synchronous breathing, often with movement of the cupula. Thoracic auscultation reveals louder than normal lung sounds in early phases. As disease progresses, harsh lung sounds with moist crackles and rales are heard over the affected lungs. Pulmonary edema may be cardiogenic, often accompanied by a murmur, gallop, or arrhythmia noted on auscultation and mild hypothermia. Other differential diagnoses include CNS disease, pneumonia (viral, parasitic, fungal, or bacterial), aspiration, pulmonary contusions, or hemoglobin abnormalities. Noncardiogenic pulmonary edema may be caused by seizures, electrocution, after an acute airway obstruction (such as after choking or near-drowning) and acute lung injury, or respiratory distress syndrome.

Thoracic radiography should be performed only when the animal is able to tolerate the procedure. Radiographs can help differentiate many of these diseases;

however, imaging should not delay therapy. Some animals may be more tolerant of ultrasonography. The thoracic focused assessment with sonography (TFAST) technique may be used to identify pleural fluid and air, examining both hemithoraces between the fifth and sixth ribs ventrally and between the seventh and ninth ribs dorsally. A pneumothorax may be present when the "slide sign" is absent; this is a linear movement noted between the visceral and parietal pleura and requires practice to identify.

Treatment: Oxygen is administered immediately via flow-by, mask, hood, or oxygen cage techniques. Sedation with a narcotic/tranquilizer combination (butorphanol 0.2–0.4 mg/kg, IV or IM, with or without acepromazine, 0.05 mg/kg, IV or IM) can relieve struggling and anxiety. Long-term continuous supplemental oxygen is best provided by a nasal oxygen catheter. The intranasal oxygen catheter is placed after topical anesthetic has been instilled into the nostril where the tube is to be inserted. Humidified nasal oxygen flow rates of 50–100 mL/kg/min deliver 40%–60% inspired oxygen while allowing the animal to be examined and the underlying disease treated. Nasopharyngeal or nasotracheal catheters or bilateral nasal cannulas may provide higher percentages of inspired oxygen. If cyanosis and decompensation persist or work of breathing is profound, intubation and positive-pressure manual ventilation or mechanical ventilation with 100% oxygen is necessary.

Catastrophic pleural space disease with rapid cardiovascular decompensation, absent lung sounds throughout the thorax, and a barrel-shaped chest suggests tension pneumothorax. A routine thoracocentesis is often inadequate for these animals, so an intercostal incision or placement of a large-bore catheter is necessary: lidocaine is injected for local anesthesia, a small skin incision is made between ribs (at the seventh to eighth intercostal space), and hemostats are used to enter the pleural space, relieving the tension within the thorax. This allows cardiovascular filling and lung reexpansion. The open pneumothorax is then managed by placing a chest tube and surgically closing the intercostal incision.

When breathing is severely compromised by pleural air or fluid without tension pneumothorax, the pleural space should be drained by thoracocentesis. The intended site is clipped and aseptically prepared (when time permits). If fluid is expected,

the needle is inserted ventrally between the sternum and costochondral junction. When air is to be recovered, the needle is inserted into the dorsal half of the thorax, above the costochondral junction. A local anesthetic is placed into the skin, subcutaneous tissue, and intercostal muscle at the site to be tapped. After the needle is inserted just through the skin, a drop of saline is placed in the hub of the needle. The needle is then gradually inserted straight into the thorax (with the needle perpendicular to the chest wall) until the saline in the needle hub moves. The movement of the saline in the hub indicates that the pleural space has been entered, although this may not always occur. The needle is immediately directed so that it lies against the parietal pleura. This prevents laceration of the lung by the needle as the lung reexpands. As soon as the pleural space is entered, the evacuation apparatus (an IV extension set, 3-way stopcock, and syringe) is attached and aspiration begins. In animals in which the pleural space cannot be emptied (eg, tension pneumothorax, ongoing hemorrhage) or when repeated chest taps are required within minutes to hours, an indwelling chest tube should be placed for continuous closed suction until the problem resolves or further therapy is performed.

Lung parenchymal disease is primarily treated using oxygen supplementation, sedation to relieve anxiety, and therapy directed at the underlying cause. Cardiogenic edema is usually associated with a gallop, murmur (determined by auscultation), arrhythmia, and/or mild hypothermia and responds well to furosemide administration (1–4 mg/kg, IV, every 1–2 hr) in all but the most severe of cases. Furosemide is more effective when delivered as a constant-rate infusion (1–2 mg/kg/hr). Cardiogenic edema can benefit from venodilation from nitroglycerin ointment (¼ in. for cats and ½ in. for larger dogs) applied topically to a shaved area of the abdomen, inguinal region, or directly to a mucous membrane; severely affected animals with normal blood pressure may benefit from a balanced vasodilator (nitroprusside, 0.5–10 mcg/kg/min), tapered up slowly and monitoring blood pressure continuously to keep the mean arterial pressure >85 mmHg. After initial stabilization, further diagnostic procedures (eg, thoracic radiography and echocardiography) aid in determining the cause and specific therapy. Animals with proteinaceous fluid (such as occurs with noncardiogenic pulmonary edema, respiratory distress syndrome, pneumonia, etc) will not respond to simple diuretic therapy. If oxygen

supplementation does not maintain $\text{PaO}_2 > 60$ mmHg (pulse oximetry or $\text{SpO}_2 > 90\%$), or if $\text{PaCO}_2 \geq 60$ mmHg, or if there is moderate to severe increases in work of breathing despite oxygen therapy, then manual or mechanical positive-pressure ventilation is required.

If respiratory failure is imminent with pulmonary fluid visible in mouth or nares, then intubation, airway suctioning, and manual bag-valve-mask ventilation with 100% oxygen are required. Elevated or postural pulmonary parenchymal evacuation (EPPE) can be performed with two or more people elevating the pet vertically, head down, while guarding the endotracheal tube. The thoracic cavity is manually compressed to assist airway and lung fluid drainage. Manual ventilation with 100% oxygen and suction of the airway should be performed between EPPE efforts.

Circulation

Diagnosis: Animals with circulatory compromise have alterations in their physical perfusion parameters (ie, heart rate, mucous membrane color, capillary refill time [CRT], rectal temperature, pulse quality, and level of consciousness). Careful auscultation of the heart for a murmur, gallop, arrhythmia, or muffled heart sounds and of the lungs for evidence of fluid is important to help identify heart failure as a cause of poor perfusion. Measurement of arterial blood pressure, central venous pressure, central venous PaO_2 , and serum lactate provide objective data for reaching resuscitation endpoints and monitoring trends of change after resuscitation.

In the early compensatory stages of hypovolemic shock in dogs, there is a rapid heart rate, pink to red mucous membranes, rapid CRT, and bounding pulses; the animal is most often alert and responsive. Animals with a significant amount of pain or anxiety may appear to be in compensatory shock; pain medications are warranted, and time for the animal to acclimate to the environment is helpful. This stage is rarely identified in cats. Tachycardia is often the first and only sign, so persistent tachycardia must be considered a sign of decreased perfusion and addressed as such. As the pathology progresses, dogs begin to have pale mucous membranes, prolonged CRT, weak pulses, tachycardia, and a decreased level of responsiveness—the classic signs of the middle or early decompensatory stage of shock. Cats have gray mucous membranes, slow CRT, weak or absent pulses, hypothermia, and a normal or low heart rate. As shock

approaches the terminal stages, the heart rate slows in both dogs and cats, and animals begin to lose consciousness. Clinical signs in this terminal stage include heart failure, pulmonary edema, severe hypotension, oliguria, and abnormal respiratory patterns. Cardiopulmonary arrest is a common sequela.

Treatment: The therapeutic goal is to deliver oxygen and substrate to the tissues. This requires a heart that effectively pumps blood and adequate hemoglobin, intravascular volume, vascular tone and patency, as well as sufficient oxygen and substrate for cellular metabolism. General guidelines for treatment of hypovolemic and distributive shock are described below, but modifications may be needed for specific animals or disease processes.

Oxygen Supplementation: Oxygen (at least 40%–60% inspired concentration) should be administered by flow-by technique, mask, hood, nasal cannula, endotracheal tube, or transtracheal catheter.

Hemostasis: Control of ongoing hemorrhage is essential for stabilization and often required before restoration of circulation. The animal must be carefully and thoroughly examined for any evidence of external hemorrhage. Direct pressure should be immediately placed over the bleeding skin site, and bleeding arteries clamped. When blood slowly oozes from a skin wound, a compression bandage should be placed. If more aggressive hemostasis is required, a blood pressure (pneumatic) cuff or tourniquet can be temporarily placed until coagulation occurs or surgical intervention is used to stop the bleeding. Tourniquets should not remain in place for >10 min.

Intrathoracic or abdominal hemorrhage may be difficult to detect and may be exacerbated when blood pressure and circulation are restored. The focused abdominal sonography for trauma (FAST) technique may be used to rapidly identify free abdominal fluid, focusing the probe on the ventral midline caudal to the xiphoid, over the urinary bladder, and on the right and left dependent flank regions. A four-quadrant abdominocentesis can be performed if ultrasound is not immediately available. The TFAST may be used to identify pleural fluid as well.

Ongoing abdominal hemorrhage is initially managed by small volume fluid resuscitation to low-normal endpoints and abdominal counterpressure (*see p 1667*). Ongoing intrathoracic hemorrhage should

be managed with thoracocentesis or a thoracostomy tube to evacuate the blood and to allow measurement of the volume lost. Exploration of these body cavities may be required for assessment and definitive hemostasis if a coagulopathy is not present. PCV of thoracic or abdominal fluid the same or higher than that of peripheral blood confirms hemorrhage. Significant volumes of cavitory hemorrhage may be collected in sterile, empty IV bags or blood transfusion bags for autologous blood transfusion, if necessary.

Intravascular Volume Replacement:

Intravenous or intraosseous catheters are used, with multiple catheters placed for rapid, large-volume infusion in dogs >30 kg body wt. Isotonic crystalloids can be administered by repeated low-volume boluses (10–15 mL/kg) until desired endpoints of resuscitation are reached (eg, low-normal cardiovascular parameters). However, the interstitium is at risk of fluid overload with crystalloids alone. The concurrent use of colloids and crystalloids can reduce the amount of crystalloid required, rapidly expand the intravascular space with a smaller volume of fluid infused, and reduce the amount of fluid extravasating into the interstitial spaces of vital organs (eg, lung, brain). Isotonic crystalloids are given with hydroxyethylstarches (eg, hetastarch) or stroma-free hemoglobin. Whole blood, stroma-free hemoglobin, or packed red cells are necessary during initial volume resuscitation when hemorrhage has been significant.

Small volume resuscitation to low-normal endpoints (measured perfusion parameters) is used to avoid volume overload or hypertension and is ideal for animals with head injury, pulmonary edema or contusions, abdominal or intrathoracic hemorrhage, heart disease, and all cats in hypovolemic shock. Isotonic crystalloids are given (10–15 mL/kg, IV), followed by hetastarch or stroma-free hemoglobin (dogs 5 mL/kg, IV; cats 1–5 mL/kg, IV, slowly), repeating the colloid infusion, to effect. The least amount of crystalloids and colloids possible are used to obtain and maintain a systolic blood pressure of 90 mmHg, restore a normal heart rate, and improve CRT and pulses. For an in-depth explanation, see p 1675.

Pain Control: Analgesia is provided during initial fluid resuscitation for optimal cardiovascular response and relief of anxiety. Narcotics are administered systemically, and local anesthetics can be infiltrated into the affected area. (See also p 2104.)

Warming: Animals in shock should be warmed during fluid resuscitation until rectal temperatures are >98°F. This is best accomplished by increasing the environmental temperature using warm air blowers or hot water bottles with blankets, warm water blankets, and IV fluid line warmers. Gastric, peritoneal, or urinary lavage may be needed for severe hypothermia. Surface warming is instituted only after initial volume resuscitation has provided enough intravascular volume to offset the peripheral vasodilation. Care must be taken in animals with cardiogenic shock or pericardial disease to avoid excessive peripheral vasodilation, because this may exacerbate a relative hypovolemia (due to decreased cardiac output).

Corticosteroids: Corticosteroids are administered when a deficiency is suspected (ie, Addisonian crisis, critical illness–related corticosteroid insufficiency). High-dose steroid administration has not been proved to reduce mortality in hypovolemic, septic, or cardiogenic shock and has been associated with increased morbidity, so it is not recommended.

Cardiovascular Support: Pharmacologic agents (positive inotropes, systemic vasodilators, and vasopressors) can be used when fluid infusion has adequately replaced intravascular volume (ie, central venous pressure >5–8 cm H₂O) but fails to restore blood pressure and perfusion, or when poor cardiac contractility is thought to contribute to hypotension. A positive inotropic agent can be administered to increase cardiac contractility in diseases such as sepsis and dilated cardiomyopathy (eg, dobutamine, initially at 2–5 mcg/kg/min, and the dosage titrated for optimal cardiac output). Stroma-free hemoglobin (dogs 5 mL/kg; cats 1–3 mL per cat, slowly) can be administered, and repeated as indicated, for its colloid effect as well as its mild vasopressor effect; it is particularly useful in animals with concurrent anemia. The initial resuscitation doses may be followed by a slow constant-rate infusion (dogs 10–15 mL/kg/day; cats 1–3 mL/hr up to 5 mL/kg/day) to maintain perfusion if the initial dose was successful and further support is anticipated. Pressor agents delivered as an IV constant-rate infusion such as dopamine (5–20 mcg/kg/min), norepinephrine (0.05–2 mcg/kg/min) or vasopressin (extra-label, 1–4 mU/kg/min) are other options to support blood pressure; they should be delivered in the smallest dosage needed to maintain arterial systolic pressure >90 mmHg. The blood flow to the

kidneys and GI tract, as well as other organs, may have been significantly impaired during shock. Urine output, heart rate, blood pressure, ECG, pulse intensity, and mucous membrane color should be closely monitored, because further vasoconstriction can worsen organ blood flow and function. If organ function declines or if arrhythmias become a problem, the IV drip should be stopped.

Hindlimb and Abdominal Binding:

When ongoing abdominal hemorrhage is suspected from trauma, hindlimb and abdominal counterpressure can improve perfusion. This procedure compresses the arteries and arterioles within the bound regions, increasing regional vascular resistance, and produces abdominal tamponade, thereby effectively slowing or arresting hemorrhage and redirecting blood flow from the venous capacitance vessels in the caudal half of the body to the more central (core) circulation. Hindlimb and abdominal counterpressure can be performed by placing a rolled towel or rolled cotton between the legs and along the ventral midline of the abdomen. This prevents the wrap from impairing ventilation or fracturing the spleen or liver. If time permits, a urinary catheter is placed. The hindlimbs and abdomen are then firmly wrapped with padded bandage material or towels, beginning at the toes of the hindlimb and moving cranially toward the xiphoid, taking care not to impede respiration. The bandage should be secured with tape or stretch bandage material wrapped in a spiral pattern starting caudally and moving cranially. Abdominal binding should be avoided in cases of intrathoracic or intracranial hemorrhage. Once perfusion has stabilized, the wrap is removed slowly by sections (releasing one section every 15 min) from the abdomen, starting at the most cranial portion and moving caudally. Any signs of decompensation warrant rapid rebinding of the region last unwrapped.

SECONDARY SURVEY

The secondary survey of emergency patients is the process of obtaining significant and thorough historical information, performing a complete physical examination, and collecting general diagnostic information. These data are used to direct the formulation of a specific diagnostic, therapeutic, and monitoring plan.

The **history** should be recorded in a concise format. The presenting complaint is obtained from the owner, who can provide

information such as when the animal was last completely normal. A chronology of the daily progression of abnormalities since the onset of signs can be useful. Background information includes past medical problems, toxicities, medications, drug and food sensitivities, blood transfusions, the date of last vaccinations, and other preventive care. Other organ systems not seemingly involved should also be historically evaluated. Details of the specific disease process are obtained and may help direct diagnostics and care.

A complete **physical examination** should be performed, working from head to tail. Particular attention is given to heart and lung auscultation for abnormalities, and to abdominal, rectal, and joint palpation for pain or enlargements. A complete neurologic and orthopedic examination is often warranted. Acute abdominal pain requires localization of the pain and auscultation of the abdomen for bowel sounds to localize the problem to the reticuloendothelial, reproductive, urinary, or GI systems; the peritoneal space; or the muscle, skin, nerves, or fat around the abdominal wall. Fever of unknown origin directs examination to the peritoneal cavity and to the reproductive, urinary, pulmonary, and cardiovascular systems.

An initial **minimum database** should consist of a PCV, total solids, glucose, and BUN. Other important diagnostics include urinalysis (before fluid administration), venous or arterial blood gas, an electrolyte panel, a CBC, and a serum chemistry panel. When coagulation disorders are suspected or surgery is anticipated, blood smears to estimate platelet number, buccal bleeding time to evaluate platelet function, and a clotting profile such as an activated clotting time or prothrombin time and activated partial thromboplastin time are warranted.

A deficit in any of the first three components of the primary survey (ie, airway, breathing, circulation) will quickly result in anaerobic metabolism due to poor oxygen delivery to the tissues. This can rapidly result in a type A lactic acidosis. Lactate can be accurately, easily, and rapidly measured with several point-of-care analyzers. Normal lactate values in dogs and cats are <2 mmol/L. Lactate levels normalize rapidly with treatment of the underlying condition of poor oxygen delivery to the tissues and is associated with improved survival. Lactate can be used along with other parameters as an endpoint of resuscitation in hypovolemic animals. Initial increases in blood lactate have been reported to be associated with an increase in complications and mortality in certain diseases in small animals.

SPECIFIC DIAGNOSTICS AND THERAPY

TRAUMA

Diagnostic and therapeutic efforts in emergency situations can be directed by the nature of the trauma. Blunt trauma is commonly associated with thoracic and abdominal bleeding, organ rupture, fractures, and neurologic injuries.

Penetrating trauma is typically localized to the path of the penetrating object, which is rarely a straight line. Falling from a height causes long bone and facial bone fractures as well as thoracic and abdominal injuries. A dog bitten by a larger dog can have deep-penetrating bite wounds, spinal injuries, major abdominal and thoracic trauma (even without penetrating wounds), and tracheal rupture from the shearing forces sustained during thrashing motions. Resuscitation of the airway, breathing, and circulation; control of hemorrhage; and pain relief are followed by a careful evaluation of the nervous system, chest, abdomen, integument, and musculoskeletal system.

The traumatized animal should be approached as if multiple injuries are present. The neck and spine should be immobilized until a thorough examination for spinal fractures or luxations is made. Thoracic auscultation for cardiac arrhythmias and the presence and quality of lung sounds should be done to identify chest injuries. The abdomen should be palpated for pain, fluid, or hernias. Extremity fractures should be supported by bandages or splinted to prevent further injury. Significant swelling may indicate ongoing hemorrhage. Because many internal injuries may not be apparent for a significant amount of time after the initial trauma occurs (12–48 hr), close monitoring is essential to allow early detection of potentially life-threatening problems. An animal that appears normal and stable on initial examination may have substantial underlying injury, making monitoring of at least physical examination parameters in the hospital (eg, respiratory and heart rates, mucous membrane color, and mentation) appropriate.

Initial diagnostic evaluation should include the minimum database before fluids are administered, if possible. Point-of-care tests should minimally include a PCV, total solids, BUN test strip, and blood glucose. When hemorrhage first

occurs, the peripheral blood PCV may be normal or even increased with a normal or decreased relative total protein level; this is a clinical indication of hemorrhagic shock in dogs and occurs because of splenic contraction. This release of RBCs into circulation may occur faster than interstitial to intravascular fluid shifts; therefore, serial PCV and total solid measurements should be monitored after trauma. Both PCV and total solids will decrease as hemorrhage and subsequent crystalloid/colloid resuscitation continues. An extended initial database includes arterial or venous blood gases, electrolyte panel, blood lactate, and prothrombin time/partial thromboplastin time. This baseline information is used to create the initial treatment plan and to provide the baseline for subsequent monitoring. Ionized hypercalcemia has been associated with a poorer prognosis after trauma and may warrant more intensive monitoring. Survey lateral radiographs of the chest and abdomen at presentation can demonstrate the initial changes resulting from thoracic and abdominal trauma. Orthogonal views should be performed as the animal's condition dictates. Ultrasound examination of the abdominal and thoracic cavities may provide additional information about internal injuries and can often be performed while fluid resuscitation is initiated.

Some scoring systems have been developed for trauma, such as the animal trauma triage score; this system assigns a number from 0 (slight or no injury) to 3 (severe injury) in the following categories: perfusion, cardiac, respiratory, eye-muscle-integument, skeletal, and neurologic. In one study assessing >200 dogs evaluated after vehicular trauma, dogs that died or were euthanized had significantly higher scores (median 6) than those that survived (median 2); higher scores were also associated with higher cost of care.

Thoracic Trauma

Pulmonary contusions, pneumothorax, cardiac arrhythmias, pleural hemorrhage, pericardial hemorrhage, rib fractures, flail chest, and diaphragmatic hernia are some of the potentially life-threatening complications that must be considered in thoracic

trauma. Oxygen supplementation and analgesics allow careful physical examination. An ECG, thoracic radiographs, blood gas analysis, and diagnostic or therapeutic centesis help determine the extent and severity of the problems.

Severe pulmonary contusions cause hypoxemia, labored breathing in a pattern consistent with parenchymal disease, and crackles and rales on pulmonary auscultation. If the animal does not improve with supplemental oxygen, pain medications, and fluid therapy, then tracheal intubation and positive-pressure ventilation with 100% oxygen are indicated. The airway should be suctioned to evacuate blood and debris that are obstructing the flow of air.

Labored breathing with asynchronous movement of the chest and abdomen and dull or quiet lung sounds is consistent with pleural air or fluid and warrants immediate thoracocentesis. Thoracocentesis should be performed before taking radiographs in animals with respiratory distress, because animals may struggle and decompensate while radiographs are being taken; assessment with ultrasound may be less stressful but should not delay therapy. When a negative pressure cannot be achieved, repeated thoracocentesis or continuous drainage of the pleural space by chest tube is required. Large quantities of whole blood removed on thoracocentesis or ongoing leakage of air after 72 hr of pleural drainage are indications for surgical exploration of the chest. Large volumes of blood aspirated during a centesis may be collected into an IV bag or blood transfusion bag, because they may be used for autologous blood transfusion.

The thoracic focused assessment with sonography technique (TFAST) can help diagnose pneumothorax, hemothorax, or thoracic wall trauma and provides an alternative to radiographs when performed by a skilled sonographer familiar with ultrasonographic changes associated with these injuries. The chest cavity should be palpated for rib fractures with displaced bone, flail segments, avulsion of ribs, torn intercostal muscles, and herniations. When flail segments impair ventilation, the segment is stabilized by securing it to an external frame or cast, formed to the shape of the chest. Penetrating bite wounds over the chest should be explored under anesthesia for debridement and drain placement; if the wound is penetrating, the thorax may be surgically entered to inspect damage to underlying tissue, repair or debride that tissue as necessary, lavage the thoracic

cavity, and place a thoracostomy tube before closure.

As the animal's condition allows, thoracic radiographs (two or three views) should be performed to assess for injury to the lungs. Many of the above-listed injuries may show up on routine radiographs; however, radiographic evidence of pulmonary contusions may not appear until 12–24 hr after the initial injury.

The heart should be auscultated and an ECG evaluated for arrhythmias. Arrhythmias may not be present at the time of injury but develop 12–48 hr after the event as myocardial contusions and hypoxemia affect the cardiac conduction system. Common arrhythmias seen after thoracic trauma include sinus tachycardia, ventricular premature contractions, and ventricular tachycardia. Treatment with lidocaine or other antiarrhythmic medications is warranted if the arrhythmias impair perfusion, if the rate is rapid and sustained (>180 bpm in dogs), if ventricular premature contractions are multifocal, or if there are prebrillatory rhythms (R on T phenomenon, torsades de pointes, ventricular flutter).

Abdominal Trauma

The extent and severity of abdominal injuries are often not initially apparent, unless there is visceral herniation outside the body cavity. The abdominal surface should be examined closely for evidence of bruising, abrasions, lacerations, protrusions, localized swelling, herniations, distention, and pain. Animals with evidence of abdominal pain that are in shock are considered to have intra-abdominal hemorrhage until proved otherwise. Rupture or laceration of the spleen or liver are the most common sources of intra-abdominal hemorrhage. However, all abdominal organs are susceptible to the shearing forces from blunt trauma. Other common sources of abdominal bleeding include avulsed mesenteric vessels, damaged muscle, or avulsion of the kidneys in the retro-peritoneal space.

Approximately 40 mL/kg (just less than half of the circulating blood volume) is necessary before free blood in the abdominal cavity will be evident by palpation or visual inspection; this volume is associated with signs of poor perfusion (shock). Smaller volumes of abdominal fluid may be apparent with radiographs, abdominocentesis, or ultrasound of the abdomen. Abdominal distention from hemorrhage may become apparent if

aggressive fluid resuscitation increases blood pressure and disrupts one or more blood clots that provided hemostasis. Small volume fluid resuscitation to achieve a low-normal blood pressure endpoint (90 mmHg systolic) is indicated to avoid sudden increases in arterial or venous pressures. When ongoing abdominal hemorrhage is confirmed, hindlimb and abdominal binding (*see* p 1667) is indicated early to reduce the amount of hemorrhage until hemostasis is accomplished.

After injury of any abdominal organ, clinical signs of organ dysfunction or hollow viscus rupture typically develop over a period of hours but may be longer or shorter depending on the nature of the injury. Acute abdominal pain is a key physical finding. Survey abdominal radiographs can demonstrate organ displacement, distention, rotation, or free abdominal gas or fluid. Fluid can be recovered by four-quadrant abdominocentesis. Using the focused assessment with sonography technique (FAST, *see* p 1665), even small amounts of free fluid in the abdomen can be identified and aspirated using ultrasound guidance.

When free fluid is not readily identified, a diagnostic peritoneal lavage can be done. A fenestrated catheter is placed into the peritoneal space, and warm isotonic saline (20 mL/kg) is infused into the abdomen. The fluid is allowed to dwell for several minutes and distribute throughout the abdomen; it is then drained and evaluated.

Clear fluid indicates that the possibility of significant abdominal hemorrhage is minimal. Fluid with a 1% PCV indicates mild abdominal hemorrhage, whereas fluid with a PCV >5% indicates significant abdominal hemorrhage that warrants careful monitoring.

Fluid obtained from the abdomen should be examined cytologically for evidence of WBCs, plant or meat fibers, and free or intracellular bacteria. Biochemical evaluation for creatinine and potassium, bilirubin, amylase, and phosphorus help identify urinary system rupture, gallbladder rupture, pancreatic injury, or ischemic bowel, respectively. Abdominal fluid glucose that is 20 mg/dL or more below peripheral blood glucose is characteristic of a septic peritonitis and warrants exploratory surgery. The abdominocentesis, peritoneal lavage, or FAST scan can be repeated in several hours if fluid from the first assessment did not indicate a significant problem but the clinical signs continue or progress. Retroperitoneal, fascial, or intramuscular

(body wall) hemorrhage or hemorrhage into the GI system can be more challenging to identify.

Criteria for emergency exploratory laparotomy include ongoing hemorrhage; inability to stabilize shock; organ rotation, entrapment, or ischemia; diaphragmatic hernia; and evidence of organ rupture or peritonitis. Some simple bladder ruptures may be amenable to medical management and placement of a urinary catheter. Surgery to repair a diaphragmatic hernia should not be delayed, particularly with gastric displacement into the thoracic cavity, respiratory compromise, or ongoing hemorrhage.

Retroperitoneal, severe fascial compartment hemorrhage (associated with pelvic fractures), or hemorrhage into a hollow viscus is suspected in acutely traumatized animals that still have signs of a declining PCV/total solids, nonresponsive hemorrhagic shock, and no significant findings on abdominocentesis, peritoneal lavage, or FAST scan. Radiographs typically show expansion and loss of detail in the retroperitoneal space. An IV pyelogram should be done to help delineate disruption in the renal vascular supply or in the retroperitoneal portion of the ureter before proceeding with exploratory surgery in this situation.

CARDIOPULMONARY RESUSCITATION

The success of cardiopulmonary resuscitation (CPR) efforts depends on many factors, including the underlying cause of the arrest, the timeliness and effectiveness of the intervention, and the preparedness of the team administering CPR. Overall prognosis of recovery from cardiopulmonary arrest (CPA) with CPR efforts is as high as 35%–44%; however, only <10% of animals survive to discharge. Animals with CPA associated with anesthesia have a better prognosis. The American College of Veterinary Emergency and Critical Care developed the first set of guidelines for veterinary CPR; this effort was termed the Reassessment Campaign on Veterinary Resuscitation (RECOVER) and is available at www.acvecc-recover.org. CPR is divided into several sections: prevention and preparedness; basic cardiac life support (BCLS) promoting oxygenation, ventilation, and circulation; advanced cardiac life support (ACLS) using electrocardiographic evaluation of cardiac rhythms, administration of drugs, and defibrillation when necessary; monitoring during CPR; and postresuscitation management, which involves intensive monitoring of common

complications after arrest as well as diagnosis and treatment of underlying conditions that led to the cardiopulmonary arrest.

Prevention and Preparedness

In an effort to have the entire veterinary team prepared for CPR on any animal, RECOVER guidelines recommend standardization and regular audit of resuscitation equipment as well as immediate availability of cognitive aids and descriptive CPR algorithms (eg, dose charts, checklists), which are available through the RECOVER website. Cognitive skill training and didactics should be incorporated for all veterinary team members on a regular basis. Assigning a leader and having specific leadership training, including debriefing after any CPR efforts, are recommended as well. Each team member should be familiar with available medical equipment and his or her role during CPR.

Basic Cardiac Life Support

When CPA is recognized, CPR efforts should begin immediately. Early recognition and intervention is essential. Palpation of pulses is not recommended before initiating compressions, because this will delay intervention. Mouth-to-nose resuscitation should be performed until endotracheal intubation and positive-pressure ventilation with 100% oxygen can be accomplished. The compression to ventilation ratio should be 30:2. Once the airway is established, it is imperative to confirm placement with thoracic auscultation, visualization, palpation, and ETCO₂ monitoring, as well as to secure the tube with a tie-in. Ventilations should be provided at a rate of 10 breaths/min, with a volume of 10 mL/kg and an inspiratory time of 1 sec. Ideally, these breaths are provided with a portable bag-valve-mask apparatus.

Simultaneous with ventilation, circulation should be promoted in small animals by compressing the chest externally. Compressions should be performed with the animal in lateral recumbency (or dorsal recumbency for barrel-chested animals, such as Bulldogs). Compressions should be performed over the widest part of the thorax using the "thoracic pump" technique. In keel-shaped animals (such as Greyhounds or cats), compressions may be performed directly over the heart (at the fourth and fifth intercostal space) using the "cardiac pump" technique. The compression rate should be 100–120 compressions/min regardless of size. Each compression should be delivered quickly in a cough-like

fashion and should compress the chest wall $\frac{1}{4}$ to $\frac{1}{2}$ of the width and allow full recoil of the chest. When the cardiac pump technique is used, direct compression of the ventricles of the heart contribute to forward blood flow; in the thoracic pump technique, changes in thoracic pressure are the important mechanism to generate forward blood flow. Simultaneous ventilations and compressions should be done in 2-min cycles; individuals performing the ventilation and compressions should change functions every 2 min to prevent fatigue and less-effective compressions. Interruptions to chest compressions to assess ECG or auscult the heart should be minimal. Interposed abdominal compressions may be added for animals without abdominal disease if adequately trained staff is available. This is performed by placing both hands on the abdomen and compressing quickly, timing the compression to be done between chest compressions.

The goal is to improve venous return to the heart during the diastolic phase of the compression cycle. Monitoring CPR (*see below*) may necessitate a change in CPR technique.

Advanced Cardiac Life Support

In ACLS, an ECG is obtained to characterize arrhythmias, followed by drug administration or defibrillation as indicated. The purpose is to reestablish electrical and mechanical activity of the heart. The major arresting rhythms in veterinary medicine include sinus bradycardia, asystole, pulseless electrical activity (PEA, previously termed electromechanical dissociation), and ventricular fibrillation or flutter. Drugs are selected based on the arrhythmia or known/suspected underlying disease and can be administered by intravenous, intraosseous, or intratracheal routes (*see TABLE 2*). Drugs that can be administered intratracheally include naloxone, atropine, vasopressin, epinephrine, and lidocaine (best remembered by the acronym NAVEL); the dosage for all drugs is usually doubled when administration is intratracheal. Intracardiac administration of drugs is no longer recommended, because arrhythmias, myocardial hemorrhage, and myocardial vessel laceration may occur.

If the animal is known or suspected to be hypovolemic, isotonic balanced crystalloid solutions should be rapidly infused to restore volume and promote perfusion. Synthetic colloids such as hetastarch, hydroxyethyl starch, dextran 70, or stroma-free hemo-

TABLE 2

DRUGS AND DEFIBRILLATION USED IN CARDIOPULMONARY RESUSCITATION

Drug	Dosage ^a	Indications
Epinephrine	Low dose (0.01 mg/kg) every 3–5 min early in CPR; high dose (0.1 mg/kg) after prolonged CPR; 10 times the dose may be required when given intratracheally	Asystole, ventricular fibrillation, PEA ^b
Atropine	0.1 mL/5 lb (0.5 mg/mL solution)	Sinus bradycardia, asystole, or PEA associated with high vagal tone
Sodium bicarbonate	1 mEq/kg (1 mEq/mL solution)	Severe metabolic acidemia associated with prolonged (>10–15 min) cardiopulmonary resuscitation efforts (must be adequately ventilated to be effective), hyperkalemia
Calcium gluconate	1 mL/5–10 kg (2% solution without epinephrine)	Routine use not recommended; treat cases with documented hypocalcemia (or severe hyperkalemia)
Amiodarone	5 mg/kg	Refractory ventricular fibrillation or pulseless ventricular tachycardia
Magnesium sulfate	30 mg/kg	Hypomagnesemia, torsades de pointes
Lidocaine	2–4 mg/kg	Pulseless ventricular tachycardia, ventricular fibrillation resistant to defibrillation
Vasopressin	0.4–0.9 U/kg	Combined with or as a substitute for epinephrine every 3–5 min (asystole, bradycardia, PEA)
Naloxone	0.02–0.04 mg/kg	To reverse opioids
Defibrillation	4–6 joules/kg external (monophasic), 2–4 joules/kg external (biphasic), 0.2–1 joules/kg internal	Single shock, resume CPR efforts immediately after for one cycle (2 min), dose escalation may occur

^a Dosage should be doubled if given via intratracheal route.

^b PEA = pulseless electrical activity

globin rapidly expand the intravascular volume with much smaller infusion volumes required. Overzealous fluid administration can result in fulminant pulmonary edema due to poor myocardial contractility and arrhythmias. Fluids should not be adminis-

tered to euvoletic animals, because the increase in central venous pressure may reduce myocardial and cerebral blood flow. Metabolic alterations such as hyperkalemia, hypocalcemia, and severe acidosis should be treated when evident but not otherwise.

Impedance threshold devices may be considered an adjunct to therapy and used only on animals weighing >10 kg.

If closed chest BCLS is unsuccessful (as determined by lack of spontaneous respiration or inability to generate detectable forward blood flow) after 5–10 min, open-chest CPR (*see below*) is indicated. Instances when open-chest CPR is indicated during initial BCLS include unwitnessed arrest, recent abdominal or thoracic surgery, suspected pleural or pericardial disease, trauma or pathology of the chest or abdominal wall with blood loss, diaphragmatic hernia, and in larger dogs in which external compressions are unlikely to generate an adequate forward blood flow.

Arrhythmias of Cardiac Arrest

Asystole: Asystole appears as a flat line on the ECG and suggests complete absence of electrical activity. In arrest situations known or suspected to be associated with hyperkalemia, calcium gluconate should be administered. Regular insulin at 0.2 U/kg, followed by glucose at 1–2 g/U of insulin, diluted to 25%, temporarily reduces serum levels of potassium. Epinephrine or vasopressin, with or without atropine can be administered in an attempt to generate impulses. Fine ventricular fibrillation may look like asystole, and for this reason, open-chest heart massage and direct observation of myocardial activity are warranted early with this arrhythmia; if fibrillation is visualized, defibrillation is indicated.

Ventricular Flutter: This rhythm is more chaotic than ventricular tachycardia and is prefibrillatory. Lidocaine is the drug of choice to block the excited focus. If lidocaine is ineffective after two boluses and perfusion is absent, defibrillation may be required.

Ventricular Fibrillation: This rhythm implies that multiple foci within the ventricles are firing rapidly and independently, resulting in no coordinated mechanical activity. There are no ventricular contractions and no cardiac output. The goal is to abruptly stop the electrical activity and allow one strong (hopefully normal) electrical rhythm to take over. Defibrillation is more successful when there are few, strong foci (coarse fibrillation) than when there are multiple, weak foci (fine fibrillation).

Pulseless Electrical Activity (PEA): The ECG tracing can be normal or show an arrhythmia (commonly a bradyarrhythmia

of ventricular or supraventricular origin), but the heart has no muscular activity associated with the electrical activity, ie, no contractions and no cardiac output and, subsequently, no pulses. In this arrhythmia, it is vital that thoracic auscultation be performed in tandem with central pulse (femoral arterial) palpation and ECG evaluation. There are no heart sounds or pulse activity. However, severe hypovolemia, pericardial effusion, and significant accumulation of fluid or air in the pleural cavity can prevent detection of normal heart sounds. The ECG associated with these conditions demonstrates tachyarrhythmias, in contrast to the usually normal or slow rate of PEA. Atropine and epinephrine or vasopressin may be given in an attempt to correct this arrhythmia. Defibrillation may be attempted with pulseless ventricular tachycardia.

Sinus Bradycardia: Sinus bradycardia on the ECG has P, QRS, and T waves that appear normal, except they occur at a much slower rate. This arresting rhythm may be caused by many disease processes, such as high vagal tone due to GI, urinary, or thoracic disease, and hyperkalemia due to urinary obstruction or rupture and prolonged CPA with CPR efforts. Treatment of known or suspected hyperkalemia with calcium gluconate, insulin, and dextrose with or without sodium bicarbonate may be necessary. Atropine is indicated in this arrhythmia.

If the CPA is believed to be associated with drug administration, a reversal agent should be administered in addition to treating arrhythmias in ACLS. Benzodiazepines such as diazepam and midazolam are reversed with flumazenil, opioid medications such as fentanyl and morphine-related drugs can be reversed with naloxone or partially reversed with butorphanol, xylazine can be reversed with yohimbine, and dexmedetomidine can be reversed with atipamezole. If inhalant anesthesia was used, it should be discontinued and the anesthetic circuit flushed with fresh oxygen.

Open-Chest Cardiopulmonary Resuscitation

(Emergency thoracotomy)

If possible, a quick clip of the hair along the intended incision site is helpful. Usually, there is no time for a full aseptic preparation of the area. A scalpel blade or Mayo scissors are used to incise the skin and subcutaneous tissues along the cranial border of the fourth

or fifth rib from the spine to sternum. A Carnall forceps or Mayo scissors are used to bluntly dissect through the underlying muscle tissues and push through the pleura. Ventilations should be discontinued momentarily, and the instrument should be guarded with a thumb and forefinger as the pleura is entered to prevent injury to the heart or lungs. After the pleura is entered at the ventral aspect of the incision, Mayo scissors are used to incise the muscles dorsally along the entire length of the intercostal space, along the cranial aspect of the rib. Care should be taken to avoid incising the internal thoracic vessels running parallel and lateral to the sternum. After the chest cavity is opened, manual ventilations should continue, and the pericardiodiaphragmatic ligament elevated and incised with scissors, extending the incision dorsally to just ventral to the phrenic nerve. The heart is then lifted out of the pericardial sac and observed for any coordinated spontaneous contractions. If no cardiac contractions are noted, the heart is grasped with one or both hands and compressed progressively from the apex to the base. The compression is then released to allow the cardiac chambers to refill with blood. If fine or coarse fibrillation of the heart muscle is noted, internal defibrillation should be performed.

The descending aorta can be isolated and temporarily cross-clamped to direct blood flow to the brain. Aortic cross-clamping can be performed with atraumatic vascular clamps or by using a modified Rommel tourniquet, passing a rubber tube, latex tube, or umbilical tape around the aorta with the assistance of curved hemostats and then clamping on the tube to occlude aortic flow. Aortic cross-clamping can be performed for 10 min without serious complications (from lack of blood flow to the spinal cord).

An ECG is evaluated and drugs given as indicated during ACLS procedures. Return of spontaneous circulation allows lavage of the thorax with large quantities of sterile, warm, isotonic saline; placement of a thoracostomy tube; and surgical closure of the thorax. Cardiovascular support (see p 1665) is frequently required to maintain circulation while the underlying cause of the arrest is treated.

Monitoring

End-tidal CO_2 (ETCO_2) should be measured in intubated patients at risk of having CPR and is a useful monitoring tool during CPR efforts. Using an ETCO_2 reading along with visualization, palpation, and auscultation can help

confirm endotracheal intubation. ETCO_2 may also be an early indicator of return of spontaneous circulation (ROSC) and effectiveness of CPR efforts (when minute ventilation is consistent). An ETCO_2 of <10 mmHg indicates esophageal intubation, ineffective CPR technique, incorrect placement of endotracheal tube, or hyperventilation (if adequate perfusion is established). An ETCO_2 reading of 12–18 mmHg indicates an ROSC, and a reading of >45 mmHg may indicate hypoventilation or increased CO_2 delivery to the lungs after ROSC occurs.

Routine monitoring of ECG is essential during CPR to allow identification and specific therapy of arrhythmias. Palpation of pulses either to detect CPA or to monitor effectiveness of CPR efforts is not recommended because of the insensitive nature of this test. Use of Doppler monitoring (on eyes or peripheral arteries) to detect CPA or monitor efforts of CPR is also not recommended.

Use of blood samples may help guide therapy in some instances during CPR. Centrally collected samples are ideal; however, most patients do not have a central catheter. Peripheral blood samples do not necessarily reflect the central circulation but may help guide therapy in some instances (such as hyperkalemia). It is not recommended to monitor with arterial gas samples or pulse oximetry; these require pulsatile arterial flow, which is inadequate during CPR.

Close monitoring of an animal after arrest is vital, because significant abnormalities of acid-base and electrolytes (especially hyperkalemia) are common and may require additional treatment. Parameters such as ECG, blood pressure, neurologic status, pulse oximetry, ETCO_2 , and venous blood gases should be monitored closely. Blood pressure support with dopamine, dobutamine, other pressor agents, or stroma-free hemoglobin, as indicated, may be required to maintain cardiac output. Body temperature, glucose, and lactate may provide additional information.

With anaerobic metabolism that occurs during shock and cardiopulmonary arrest, blood lactate levels (see p 1686) rise dramatically (normal levels are <2 mmol/L). With ROSC, lactate levels may rise dramatically and then resolve with appropriate treatment.

Postresuscitation Care

Routine use of large volumes of fluids is not recommended and should be avoided in animals with congestive heart failure. It is important to use resuscitation

endpoints during post-CPA care to normalize venous oxygen content, lactate, blood pressure, central venous pressure, PCV, and oxygen saturation. Medications to help reduce cerebral edema, such as mannitol and furosemide, can be administered after CPA and are often recommended to help decrease cerebral edema. Routine mechanical ventilation is not routinely recommended but reasonable in animals that are hypercapneic or

hypoxemic. Vasopressors and positive inotropes are reasonable when needed. Animals with open-chest CPR will require control of hemorrhage, pleural lavage, placement of a chest tube, perioperative antibiotics, and closure of the thoracic cavity. A large percentage of animals that sustain a CPA will have another episode of CPA. Treatment of the underlying condition that led to the CPA is essential to help prevent recurrence.

FLUID THERAPY

Cardiac function; intravascular volume; and vascular tone, integrity, and patency are critical to normal circulation. An abnormality in one or more of these components of circulation leads to stimulation of the sympathetic nervous system, which results in compensatory changes to maintain perfusion. The hemodynamic and cellular changes that develop as a result of these abnormalities are called shock. As shock progresses, oxygen and substrate delivery to the tissues becomes insufficient to meet energy requirements for cellular maintenance and repair. If shock progresses and cellular energy demands cannot be met, the ensuing organ failure leads to death. Early recognition of the type and stage of shock is vital to establishing a successful fluid therapy plan; timely intervention with appropriate therapy will prevent or decrease organ injury and/or death.

Shock is typically classified into three categories: hypovolemic, cardiogenic, and distributive. Hypovolemic shock develops when there is a blood volume deficit $\geq 15\%$; this may be from hemorrhage or other fluid losses (eg, as occurs with severe vomiting and diarrhea). Cardiogenic shock results when the heart fails as a pump; common causes include pulmonary emboli, cardiac tamponade, valvular insufficiency, cardiomyopathy, and cardiac arrhythmias. Distributive shock is caused by maldistribution of blood flow away from the central circulation as a result of peripheral vasodilation; it can be caused by conditions such as anaphylaxis, corticosteroid deficiency (hypoadrenocorticism and critical illness–related corticosteroid insufficiency), and systemic inflammatory diseases that lead to systemic inflammatory response syndrome (SIRS). The different types of

shock may have different hemodynamic profiles during the early and middle stages. Frequently, more than one type of shock is present, with hypovolemia likely to play a role in each form. Rapid and aggressive fluid resuscitation yields the best outcome, with hemostasis used as required. In veterinary patients, many stages and categories of shock will respond to fluid resuscitation alone; medications such as antiarrhythmics and inotropes may be necessary for primary cardiogenic shock, and vasopressor agents may be necessary for distributive shock. The ability to create an effective fluid resuscitation plan depends on an understanding of the different body fluid compartments and the dynamics of fluid movement and distribution between fluid compartments.

BODY FLUID COMPARTMENTS AND FLUID DYNAMICS

There are three major fluid compartments; intravascular, interstitial, and intracellular. Fluid movement from the intravascular to interstitial and intracellular compartments occurs in the capillaries. A capillary “membrane,” which consists of the endothelial glycocalyx, endothelial cells, and the subendothelial cell matrix, separates the capillary intravascular space from the interstitial fluid compartment. This capillary “membrane” is freely permeable to water and small-molecular-weight particles such as electrolytes, glucose, acetate, lactate, gluconate, and bicarbonate. Gases such as oxygen and carbon dioxide diffuse freely through this membrane to enter or exit the intravascular compartment.

The interstitial compartment is the space between the capillaries and the cells. Fluids

support the matrix and cells within the interstitial space. The intracellular compartment is separated from the interstitial space by a cell membrane. This membrane is freely permeable to water but not to small- or large-molecular-weight particles. Any particle movement between the interstitium and the cell must occur through some transport mechanism (eg, channel, ion pump, carrier mechanism).

Fluids are in a constant state of flux across the capillary endothelial membrane, through the interstitium, and into and out of the cell. The amount of fluid that moves across the capillary "membrane" depends on a number of factors, including capillary colloid oncotic pressure (COP), hydrostatic pressure, and permeability, which is dictated by factors such as the endothelial glycocalyx and pore sizes between the cells. The natural particles in blood that create COP are proteins: primarily albumin but also globulins, fibrinogen, and others. The hydrostatic pressure within the capillary is the pressure forcing outward on the capillary membrane generated by the blood pressure and cardiac output. Fluid moves into the interstitial space when intravascular hydrostatic pressure is increased over COP, when membrane pore size increases, or when intravascular COP becomes lower than interstitial COP.

THE FLUID RESUSCITATION PLAN

In hypovolemic shock, compensatory neuroendocrine responses are initiated to restore blood volume and meet metabolic demands that occur during acutely decreased cardiac output states, increasing ATP demands. When perfusion continues to be compromised despite these mechanisms, cells can no longer generate ATP, compensatory mechanisms become exhausted, and decompensatory shock ensues. An adequate fluid resuscitation plan is necessary to optimize survival.

The fluid resuscitation plan should include the following steps: 1) determine where the fluid deficit lies, 2) select fluid(s) specific for the patient, 3) determine resuscitation endpoints, and 4) determine the resuscitation technique to be used.

Determination of the Fluid Deficit

Loss of fluid volume from the intravascular fluid compartment is manifested by poor perfusion (shock) and inadequate tissue oxygenation. This volume deficit results in a lower vessel wall tension. Decreased wall tension in the aortic arch and carotid arteries results in decreased stimulation of the

baroreceptors. This decreased rate of firing, sent via the glossopharyngeal and vagus nerves to the medulla oblongata, results in decreased inhibition (stimulation) of the sympathetic system. Stimulation of the sympathetic nervous system is manifested by clinical changes in heart rate, pulse intensity, blood pressure, capillary refill time, mucous membrane color, level of consciousness, and rectal temperature. These physical perfusion parameters, combined with blood pressure, are used clinically to detect intravascular volume deficits. Most animals with an intravascular deficit (poor perfusion) also have concurrent extravascular (interstitial and intracellular) deficits.

Fluid deficit in the interstitial and intracellular spaces causes clinical signs of dehydration. Physical findings are used to estimate the percentage of dehydration. Semidry oral mucous membranes, normal skin turgor, and eyes maintaining normal moisture indicate 4%–5% dehydration. Dry oral mucous membranes, mild loss of skin turgor, and eyes still moist indicate 6%–7% dehydration. As dehydration becomes more severe, significant quantities of fluid shift from the intravascular space into the interstitium, causing concurrent perfusion deficits with dehydration. Dry mucous membranes, considerable loss of skin turgor, retracted eyes, acute weight loss, and weak rapid pulses (concurrent intravascular deficit) indicate 8%–10% dehydration. Very dry oral mucous membranes, complete loss of skin turgor, severe retraction of the eyes, dull eyes, possible alteration of consciousness, acute weight loss, and thready, weak pulses indicate $\geq 12\%$ dehydration.

The physical guidelines to estimate dehydration are misleading in two common clinical situations. Chronically emaciated and geriatric animals may have metabolized the fat from around the eyes and the collagen in the skin, resulting in poor skin turgor and sunken eyes despite normal hydration. Animals with rapid fluid loss into a third body fluid space (a space within the body cavity where fluid from the local interstitial and intravascular spaces leak) have rapid fluid shifts from the intravascular compartments into these spaces before clinical evidence of interstitial fluid loss is seen. Both situations require evaluation of mucous membrane and eye moisture, PCV, and total solids before dehydration can be estimated.

Selection of Fluids

Fluids must be administered that will concentrate within the body fluid compartment where the volume deficit lies. Crystalloids are water-based solutions with

small-molecular-weight particles, freely permeable to the capillary membrane. Colloids are water-based solutions with a molecular weight too large to freely pass across the capillary membrane. Colloids are thought of as intravascular volume replacement solutions, and crystalloids as interstitial volume replacement solutions.

Crystalloids: The small-molecular-weight particles in crystalloids are primarily electrolytes and buffers (see TABLE 3). When the sodium concentration of the solution is equivalent to that of the (red blood) cell, the solution is called isotonic. Intravascular administration of isotonic crystalloids (eg, lactated Ringer's, 0.9% saline) will result in interstitial volume replacement and minimal intracellular fluid accumulation. More than 75% of the isotonic crystalloid administered IV can move into the extravascular space within 1 hr in a healthy animal. This is because of the normal fluid shifts between fluid compartments. Hypotonic fluids (eg, 5% dextrose in water, half-strength saline) will result in intracellular water accumulation and should not be used as resuscitation fluids. Hypertonic solutions (eg, 7% NaCl) contain higher concentrations of sodium and are best used when hydration is normal and concurrently with other fluids.

Crystalloids are considered buffered when they contain molecules (such as

acetate, gluconate, and lactate) that are converted to bicarbonate in the liver, equilibrating the pH of the fluid to normal blood pH (7.4). Normal saline (0.9%) is isotonic but not buffered; it is used initially for specific clinical problems, including hyponatremia, hypernatremia, hypercalcemia, hypochloremic metabolic alkalosis, head trauma, and oliguric renal failure.

Crystalloids are considered balanced when they contain electrolytes in addition to Na and Cl (such as K, Mg, Ca), making them similar to plasma. Lactated Ringer's is an example of a balanced solution; normal saline is not balanced.

The particular crystalloid to administer is determined by the measured or estimated sodium and potassium concentrations and by the osmolality of both the animal's serum and the fluid to be administered (see TABLE 3). Most clinical problems will benefit from the use of buffered, balanced, isotonic crystalloids (eg, lactated Ringer's) as part of the resuscitation fluid plan.

Sodium Content: When serum sodium measurements are normal, a balanced isotonic electrolyte solution can be used for volume replacement. Serum sodium levels that are moderately to severely decreased (<130 mEq/L) or moderately to severely increased (>170 mEq/L) may contribute to serum osmolality changes and result in neurologic abnormalities. Care must be

TABLE 3 CRYSTALLOIDS

Crystalloid	Tonicity	Na ⁺	Cl ⁻	K ⁺	Ca ⁺²	Osmolality (mOsm/L)	pH
Lactated Ringer's solution	Isotonic	130	109	4	3	273	6.7
Plasmalyte-A®	Isotonic	140	103	5	0	294	7.4
Normosol-R®	Isotonic	140	98	5	0	295	7.4
Normal saline (0.9%)	Isotonic	154	154	0	0	308	5.7
Dextrose (2.5% in 0.45% saline)	Isotonic	77	77	0	0	280	4.5
Dextrose (5%) in water	Hypotonic	0	0	0	0	253	5.0

Normosol-M® with 5% dextrose	Hypertonic	40	40	13	0	363	5.2

Electrolyte units are mEq/L.

taken not to increase or decrease the sodium concentration too quickly, which may result in cerebral edema or dehydration (and can lead to intracranial hemorrhage). In general, sodium concentrations should not be altered by >0.5 mEq/L/hr or 8–12 mEq/L/day. This allows for increased or decreased osmolality of neurons to adjust over time and avoids cerebral edema or dehydration. Crystalloids are also classified as either replacement or maintenance fluids. Replacement fluids are intended to replace fluids lost from the body (such as through hemorrhage, vomiting, diarrhea, etc) and often contain a sodium concentration near that of plasma (such as lactated Ringer's or 0.9% saline); these fluids result in excessive concentrations of sodium if given over prolonged periods of time (>24 – 72 hr) or for animals with free water loss; however, they are ideal resuscitation fluids for animals with sodium-rich fluid losses. Maintenance fluids contain significantly less sodium (such as half-strength saline or 5% dextrose in water) and are intended for animals that have free water loss or require prolonged fluid administration. Replacement fluids given to an animal with free water deficits or for prolonged periods of time (without access to water) will result in hyponatremia and hyperosmolality.

Serum sodium alterations with fluid administration ($\Delta[\text{Na}]$) can be estimated using the following formula:

$$\Delta[\text{Na}] = \frac{([\text{Na}]_{\text{fluid}} - [\text{Na}]_{\text{patient}})}{(\text{total body water} + 1)}, \text{ in which total body water} = 0.6 \times \text{body wt (kg)}$$

In animals with decreased serum sodium content, volume replacement should be with isotonic saline (0.9%) or other replacement/isotonic fluids. Increased serum sodium values most commonly reflect a loss of solute-free water. The animal should be perfused and hydrated using isotonic saline or other replacement/isotonic fluids. The free water can then be replaced, if necessary, using 2.5% dextrose in half-strength lactated Ringer's, 2.5% dextrose in half-strength saline, 0.45% saline, or 5% dextrose in water when hyponatremia persists. This must be done carefully, and the sodium concentration lowered slowly. Desmopressin may be required if hyponatremia persists after appropriate fluid therapy, especially when the animal has hyponatremia or head injury.

Potassium Content: When serum potassium estimates are normal, a balanced electrolyte solution can be used. Unless severe, hypokalemia can be difficult to recognize clinically. Few clinical situations warrant potassium supplementation beyond the content of lactated Ringer's or Plasmalyte-A[®] during initial volume replacement. Once the animal has been stabilized, potassium chloride should be added to the fluids, administered at ≤ 0.5 mEq/kg/hr. This rate may be increased when severe hyperkalemia (<2 mEq/L) is associated with catastrophic clinical signs, (eg, respiratory distress/hypoventilation from paresis of the diaphragm or generalized lower motor paresis or paralysis). The serum potassium level must be closely monitored with more rapid infusions. More commonly, potassium chloride is added to 1 L of balanced isotonic crystalloids

TABLE 4 GUIDELINE FOR POTASSIUM SUPPLEMENTATION IN DOGS AND CATS

Serum Potassium Concentration (mEq/L)	mEq KCl to Add to 1 L of Maintenance Fluids
<2.0	80
2.1–2.5	60
2.6–3.0	40
3.1–3.5	25–30
3.6–5.0	20
>5.0	none

administered as maintenance fluids based on serum potassium concentration (see TABLE 4). Serum potassium concentration should be monitored closely during continued therapy. Potassium phosphates may be used if a concurrent phosphorus deficiency is present.

In animals with hyperkalemia, fluids should be selected carefully. When oliguric renal failure is suspected as the cause of the hyperkalemia, potassium-free solutions, such as 0.9% saline, are used for volume replacement. Clinical conditions requiring potassium-free solutions include oliguric renal failure, heat stroke, adrenal insufficiency (Addison disease), and massive muscle breakdown. After volume replacement and fluid diuresis resolve the hyperkalemia, a balanced electrolyte solution should be used. These solutions have a normal pH and promote potassium excretion. Recent evidence suggests that with hyperkalemia secondary to feline urinary obstruction, any isotonic balanced fluid can be used, with minimal concern for increasing serum potassium as long as the underlying obstruction is treated.

Osmolality: Osmolality is defined as the number of solute particles per unit of solvent. Serum osmolality can be calculated using the following formula:

$$\text{Osmolality (mOsm/kg)} = 2([\text{Na}^+] + [\text{K}^+]) + [\text{glucose}]/18 + [\text{BUN}]/2.8$$

Normal serum osmolality is 290–310 mOsm/L. Fluids that do not contribute significantly to serum osmolality should be used for volume replacement.

Hyperosmolar solutions include hypertonic saline, Normosol-M® with 5% dextrose, or any isotonic fluid that has glucose or hypertonic saline added. Except for hypertonic saline, the hyperosmolar glucose-containing solutions are meant to be maintenance solutions used in animals in which fluids are not shifting rapidly from the vascular compartment to a third body fluid space. They are usually not used as volume replacement solutions.

Hypertonic saline provides a supra-normal concentration of sodium and is generally given in a 3%, 7%, or 7.5% IV solution. The effect is to rapidly draw water from the interstitial space into the intravascular space, rapidly expanding the intravascular volume. Hypertonic saline may also decrease cellular swelling and improve myocardial contractility. If the animal has concurrent interstitial fluid deficits (dehydration) or a disease that results in free water loss (eg, hyperther-

mia, diabetes, etc), administration of hypertonic saline could result in severe hyperosmolality with neurologic complications. Because hypertonic crystalloid solution will leak into the interstitium in <1 hr, combining hypertonic saline with a colloid is recommended to offset the interstitial edema resulting from interstitial extravasation.

Colloids: When colloids are to be administered, it must be decided whether a natural colloid (eg, plasma, albumin, or whole blood) or a synthetic colloid (see TABLE 5) is to be used. When the animal requires RBCs, clotting factors, antithrombin III, or albumin, blood products are the colloids of choice.

When the initial goal is to rapidly improve perfusion in an animal with adequate RBCs, a synthetic colloid can achieve the desired volume expansion rapidly. Choices of synthetic colloids include dextran, hydroxyethyl starch (HES), and stroma-free hemoglobin.

Dextrans are polysaccharides composed of linear glucose residues. They are produced by the enzyme dextran sucrose during growth of various strains of *Leuconostoc* bacteria in media containing sucrose. Dextrans are isotonic and can be stored at room temperature. Dextran is broken down completely to CO₂ and H₂O by dextranase present in spleen, liver, lung, kidney, brain, and muscle at a rate approaching 70 mg/kg every 24 hr. In normal dogs, dextran 70 increases plasma volume 1.38 times (138%) the volume infused.

Hemostatic changes in healthy experimental dogs given dextran 70 include an increase in the buccal mucosal bleeding time and partial thromboplastin time and a decrease in von Willebrand factor antigen and factor VIII coagulant activity, without clinical bleeding. Dextran copolymerizes with the fibrin monomer, destabilizing clot formation. Blood glucose levels may be increased during dextran metabolism. Dextran 70 may cause a change in the total solids value that does not reflect actual protein content and may interfere with blood crossmatching. Moderate to life-threatening reactions in dogs have been rare. Dextran 70 is being used much less commonly in favor of other colloids, and dextran 40 is not recommended because it is known to cause renal injury.

Hydroxyethyl starch (HES) is the parent name of a polymeric molecule made from a waxy species of either corn or potatoes and is composed primarily of

amyopectin (98%). HES molecules vary in size from ten thousand to several million daltons (average 70–670 thousand daltons). The disappearance of HES molecules from the body depends primarily on their rate of enzymatic degradation by α -amylase and subsequent renal excretion. Other methods of elimination include absorption by tissues (liver, spleen, kidney, and heart), uptake by the reticuloendothelial system, and clearance through bile. Blood α -amylase-mediated hydrolysis (primarily at the C6 position) reduces the molecular weight to <72,000 daltons; these smaller particles are more osmotically active but eliminated at a faster rate through the kidney. Metabolism of HES retained in tissue is probably performed by cytoplasmic lysosomes. An increase in serum amylase is to be expected without alteration in pancreatic function.

Along with molecular weight, the degree of molar substitution, which is the number of glucose units on the starch molecule that have been replaced by hydroxyethyl units, is the major determinant of how long the different types of HES survive in the blood.

Molar substitution rates vary from 0.35 to 0.7, and the higher the molar substitution, the longer the half-life in blood. The position of the molar substitution also impacts half-life; this can occur at the C2, C3, and C6 positions. Stereotactically, substitution at the C2 site impedes degradation by amylase, prolonging the half-life of HES; this is often referred to as the C2:C6 ratio. Higher ratios imply impeded breakdown and therefore longer half-lives in blood. When hetastarch (the most common HES) is infused at 25 mL/kg in healthy dogs, the initial increase in plasma volume is 1.37 times (137%) the volume infused; most hetastarches will expand plasma volume 100%–150%. Intravascular persistence is significantly greater than that of dextran 70, with 38% of hetastarch remaining, compared with 19% of dextran, 24 hr after infusion. Administration by constant-rate infusion may provide a constant supply of larger molecular weight particles, perhaps maintaining and augmenting plasma COP and intravascular volume in animals with albumin loss or increased capillary permeability. Most HES molecules may persist in the body for 2–7 days.

TABLE 5 SYNTHETIC COLLOIDS

Colloid	In Solution with	Molecular Weight (daltons) ^a	C2:C6 Ratio	Colloid Oncotic Pressure (mmHg)	Suggested Upper Limit (dose/kg/day)	Concentration (%)
Dextran 70	0.9% NaCl	70,000 (10,000–80,000)	NA	59	20 mL	6
Hextend™ (670/0.7)	Lactated electrolyte solution	670,000 (20,000–2,500,000)	5:1	25–30	20 mL	6
VetStarch™/ Voluven™ (130/0.4)	0.9% saline	130,000 (110,000–150,000)	9:1	36	50 mL	6
HESPAN® (600/0.4)	0.9% saline	600,000 (450,000–800,000)	5:1	25–30	20 mL	6
Stroma-free hemoglobin (Oxyglobin®)	Modified lactated Ringer's solution	65,000–130,000 (up to 500,000)	NA	20	See text	13

^aAverage, followed by range in parentheses.

Hydroxyethyl starches favor retention of intravascular fluid and prevent washout of interstitial proteins. In hypocoagulative situations, HES infusion has a great advantage over other colloids because the larger molecules remain intravascular, limiting pulmonary fluid flux. It is nontoxic and nonallergenic in dosages as high as 100 mL/kg in dogs. Many cats have a moderate reaction—nausea and occasional vomiting—with rapid infusion. However, when hetastarch is given slowly (throughout 5–15 min), this adverse effect is minimal. Renal injury, reported to occur from an osmotic nephrosis in people, has been poorly documented in dogs and cats, and allergic reactions are rare.

Hetastarch is associated with minor alterations in laboratory coagulation measurements but not with clinical bleeding unless daily minimal dosages (20–50 mL/kg/day) are exceeded. Molecular weight seems to have the biggest impact on coagulation, with larger molecular weight starches impacting coagulation to a greater degree. The proposed mechanisms of impact on coagulation include “coating” platelets or impeding platelet receptor signalling, dilution of coagulation factors, and interference with von Willebrand factor/factor VIII interaction. Dilutional effects on coagulation, cells, and proteins are produced in response to the volume expansion of the plasma. Animals that receive large volumes of HES solutions may have more oozing if surgery is performed, and diligent hemostasis is warranted.

A variety of HES solutions are currently available, each with its own advantages and disadvantages based on its molecular composition.

Stroma-free hemoglobin (Oxyglobin®) is a polymerized bovine hemoglobin-based solution that increases plasma and total hemoglobin concentration. This solution is indicated for the treatment of anemia and hypovolemia with tissue hypoxia. It has colloidal properties similar to those of hetastarch and exerts mild vasopressor activity, believed to be through scavenging of nitric oxide, a potent constitutive and inducible vasodilator. The dark hue of the solution causes discoloration of the serum (and sometimes the urine) that can interfere with some serum chemistry tests, depending on the type of analyzer and reagents used. Bilirubinuria will be present. Dosages ≤ 30 mL/kg/day have been approved for dogs, with the rate of infusion < 10 mL/kg/hr. When given to an animal with a normal blood volume, administration must be slow and carefully monitored to avoid volume

overload resulting from the colloidal and pressor properties of the solution. Oxyglobin has also been used in cats as infusions (4–25 mL/kg/24 hr) and/or rapid infusions (1–5 mL/cat). Anecdotally, the pressor effects in cats seem pronounced, and blood pressure should be monitored. Oxyglobin has been associated with development of pulmonary edema, pleural effusion, and respiratory distress, particularly in cats with underlying heart disease.

Lyophilized canine albumin is available as a 5% lyophilized solution that can be reconstituted. It has been administered to dogs with septic peritonitis and hypoalbuminemia and has been demonstrated to increase oncotic pressure, measured albumin levels, and Doppler-measured blood pressure, with increased albumin levels persisting for as long as 24 hours. Minimal adverse effects have been noted. Replacement volume in mL of albumin 5% solution (50 mg/mL) can be calculated using the following formula:

$$\text{body wt (kg)} \times 90 \text{ mL/kg} \times (\text{target albumin level [eg, 2 mg/dL]} - \text{patient's current albumin level}) \times 0.2 \text{ g/dL}$$

It may also be administered as a more concentrated solution (16% or 166 mg/mL) for hypotensive patients, at a dosage of 800 mg/kg throughout 6 hr. Human serum albumin is available as well and has been used with success in critically ill veterinary patients; however, when administered to healthy animals, severe adverse effects, including multiple organ failure, have been noted.

Blood products are important in many situations (see p 17). Animals that need clotting proteins may require frozen (or fresh frozen) plasma or cryoprecipitate, which contains concentrated amounts of factor VIII and von Willebrand factor; platelet-rich plasma may be necessary for platelet deficiencies. Animals with severe anemia or blood loss may require whole blood or packed red blood cells. Cavitary hemorrhage may allow collection of blood either with centesis or in surgery for autologous blood administration when banked blood is not available.

Fluid Selection: Interstitial and intracellular volume deficits (dehydration) are replaced by the administration of crystalloids. Intravascular volume (perfusion) deficits can also be replaced with crystalloids alone. However, when large quantities of isotonic crystalloids are rapidly administered IV, there is an immediate increase in

intravascular hydrostatic pressure, a decrease in intravascular COP, and extravasation of large fluid quantities into the interstitial spaces. By administering colloids in conjunction with crystalloids during fluid resuscitation of perfusion deficits, less total fluid volume is required (crystalloids reduced by 40%–60%), there is less tendency toward fluid overload, and resuscitation times are shorter.

Many conditions can increase capillary permeability and cause systemic inflammation (SIRS), including parvoviral diarrhea, other severe GI disease, pancreatitis, septic shock, massive trauma, heat stroke, cold exposure, burns, snake bite, and systemic neoplasia. Hetastarch or stroma-free hemoglobin are the colloids of choice for intravascular volume resuscitation when there is increased capillary permeability and loss of albumin through the capillary membrane. Using crystalloids alone in animals that require large volumes for resuscitation or that have increased capillary permeability will result in significant interstitial edema.

Many of these animals also have third-space fluid losses, most likely due to significant regional inflammation, that result in massive fluid requirements and make it difficult to predict the volume required to maintain fluid balance.

Determination of Resuscitation Endpoints

There are no “standard” formulas for crystalloid or colloid infusion that will guarantee complete volume resuscitation in a small animal. Variables such as renal function, presence of a third body fluid space, brain injury, lung injury, heart disease or failure, continued losses, or closed cavity hemorrhage require that fluid resuscitation rate and volumes be individualized for the patient. Sufficient volumes of fluid should be administered to reach desired endpoints of resuscitation. This has also been termed early goal-directed therapy. The endpoints typically reflect perfusion status and include heart rate, blood pressure, central venous pressure, mucous membrane color, capillary refill time, and pulse intensity. A resolution of an increased blood lactate to <2 mmol/dL supports adequate tissue oxygenation. More advanced endpoints, which can be used if additional instrumentation is available, include a central venous pressure of 5–8 cm H₂O, central venous oxygen saturation $>70\%$, and a urine output of at least 1–2 mL/kg/hr.

Shock will deplete cellular energy stores, with subsequent cellular and organ dysfunction. Restoring the circulation to “normal,” with normal oxygenation and perfusion parameters, may not be enough to allow sufficient ATP production for repair as well as maintenance. When an animal is suspected of having a disease process related to SIRS, such as vasodilation, increased capillary permeability, or depressed cardiac output, resuscitation endpoints are chosen for supranormal resuscitation (see TABLE 6). The goal is to deliver oxygen and glucose to the cells in higher than normal concentrations to promote sufficient energy production for both repair and maintenance of the cells.

There are situations, however, when supranormal resuscitation can be detrimental. Increased vessel wall tension can dislodge a life-saving clot in the vasculature of a traumatized animal, exacerbating hemorrhage. Brain and lung edema or hemorrhage can be worsened by aggressive and sudden increases in hydrostatic pressure. Hypotensive resuscitation provides endpoints that are at the lower limit of normal (see TABLE 6). The goal is to administer the smallest volume of fluids possible to successfully resuscitate the intravascular compartment while minimizing extravasation of fluids into the interstitium (especially brain or lungs), titrating the amount of preload to minimize excess fluid load to a potentially disabled heart, and reducing the probability of dislodging clots. Small-volume resuscitation techniques should be used to reach hypotensive resuscitation endpoints.

Determination of Appropriate Resuscitation Technique

Large- and small-volume techniques are used to reach endpoints discussed above. These doses of fluids should be administered throughout 10–15 min as a rapid IV infusion, and then the animal should be reassessed for restoration of normal clinical perfusion parameters and objective measurements of perfusion. Continual reassessment and titration of fluid doses will achieve resuscitation from shock in most cases (while the underlying disease is investigated and therapy instituted). Dogs in hypovolemic shock that require supranormal endpoint values can benefit from large-volume resuscitation techniques. Typically, an initial infusion of 20–50 mL/kg of buffered, balanced isotonic crystalloids

TABLE 6 RESUSCITATION ENDPOINTS

Monitored Parameter	Endpoints	
	"Supranormal" (high-end resuscitation)	"Hypotensive" (low-end resuscitation)
Blood pressure		
Systolic	90–120 mmHg	80–90 mmHg
Mean arterial	80–90 mmHg	60–80 mmHg
Central venous pressure	6–8 cm H ₂ O	3–5 cm H ₂ O
Heart rate ^a		
Dog	<140 bpm	<140 bpm
Cat	160–200 bpm	160–200 bpm
Capillary refill time	1–2 sec	1–2 sec
Pulse intensity (femoral)	Strong	Strong
Resuscitation technique		
Dog	Large volume	Small volume
Cat	Small volume	Small volume
Clinical indications	SIRS diseases Cortisol deficiency (hypoadrenocorticism, critical illness-related corticosteroid insufficiency) Anaphylaxis	Heart failure Closed cavity hemorrhage Ongoing hemorrhage Brain disease Lung edema Oliguric renal failure

^a After appropriate analgesia

is given, followed by 5–15 mL/kg of a hydroxyethyl starch solution. When stroma-free hemoglobin is selected as the colloid, the dosage is 5 mL/kg. Additional colloids can be administered using small-volume intravascular resuscitation techniques if perfusion has not improved to the desired supranormal endpoints after the initial large volume dose of fluids. Colloids should be added immediately in any animal with proteinaceous fluid losses (SIRS disease, GI fluid losses, etc).

Whole blood products can be administered by large-volume resuscitation techniques in catastrophic hemorrhagic situations. However, initial administration of stroma-free hemoglobin will allow for a slower administration of whole blood and less chance for transfusion reaction from rapid whole blood administration.

Small-volume resuscitation techniques are recommended in hypovolemic cats and any dog with closed cavity hemorrhage, head injury, pulmonary contusions or edema, cardiogenic shock, or oliguric renal failure. An initial dosage of balanced isotonic crystalloids (10–15 mL/kg for

dogs; 5–10 mL/kg for cats) is given. An HES solution can be administered (5 mL/kg in dogs; 2–5 mL/kg in cats) throughout 1–5 min as well. The perfusion parameters are reassessed, and the initial bolus dose repeated as needed until the resuscitation endpoint is reached. When stroma-free hemoglobin is used as the colloid in dogs, the dosage is 2–5 mL/kg. Stroma-free hemoglobin is not approved for use in cats, but it has been used successfully at a dosage of 1–5 mL/cat (0.25–1 mL/kg) given slowly throughout 5 min.

Hypothermia, especially in cats, can significantly limit the cardiovascular response to endogenous sympathetic stimulus (catecholamines) and to fluid resuscitation. Active external warming with circulating water blankets should be done once fluid resuscitation has been initiated. Additional warming techniques such as warm water bottles, fluid line warmers, and warm air blowers can be used to warm cats. Aggressive volume administration without active warming of hypothermic cats can result in pulmonary edema despite continued hypotension.

ASSESSMENT OF RESUSCITATION EFFORTS

Once the fluid therapy plan is underway, ongoing assessment is critical. If adequate fluids have been administered and reasonable resuscitation endpoints have not been reached, several causes should be considered: inadequate volume administration, ongoing hemorrhage, third body fluid spacing, heart disease or pericardial fluid, severe vasodilation, vasoconstriction, organ ischemia, hypoglycemia, hypokalemia, arrhythmias, severe acidemia or alkalemia, decreased venous return, severe anemia, endocrine disease (hypoadrenocorticism or critical illness related to corticosteroid insufficiency), hypothermia, or brain pathology. These variables should be rapidly assessed and corrected. If a central venous pressure (CVP) line is available, it should be checked to see whether CVP is near the endpoints assigned (TABLE 6). If not, or if no CVP is available, a fluid challenge can be given. This typically consists of a bolus (10–15 mL/kg) of crystalloids and a bolus (5 mL/kg) of hetastarch. If the perfusion parameters improve with this challenge, then the likely cause of the nonresponsive shock is inadequate volume, and colloids are titrated to reach the desired endpoints. Ultrasound, with an experienced ultrasonographer, may be useful to assess cardiac function and/or volume status in select patients.

If fluid volume appears adequate and underlying etiologies have been addressed and treated and the animal is still hypotensive, vasopressors can be used. Oxyglobin® can be given at the dosages listed above if it has not yet been used. If stroma-free hemoglobin fails to increase the blood pressure, then dopamine is administered at 2–15 mg/kg/min as a constant-rate infusion; alternative vasopressors include norepinephrine, vasopressin, and phenylephrine. These medications are weaned once blood pressure has stabilized.

MAINTENANCE FLUID PLAN

Maintaining intravascular fluids after resuscitation from hypovolemic shock and during systemic inflammatory response syndrome disease conditions causing increased capillary permeability can be a challenge. Hydroxyethylstarch solutions or Oxyglobin® can be administered as a constant-rate infusion at 0.5–1 mL/kg/hr in dogs, or 0.25–1 mL/kg/hr in cats. Newer HES solutions may be administered at higher rates (2 mL/kg/hr) without impacting

coagulation. The dosage is adjusted to maintain an adequate mean arterial pressure and CVP. The amount of crystalloids administered with colloids must be reduced by 40%–60% of what would be administered if crystalloids were used alone. The maintenance fluid plan should address three ongoing requirements: replacement of lost interstitial volume (rehydration), maintenance fluids (for normal homeostasis), and replacement of ongoing losses. The volume of rehydration fluids required is determined by reassessing hydration parameters after resuscitation, using the following formula: % dehydration $\times$ body wt (kg) $\times$ total body water (0.6). This volume is commonly administered throughout 4–12 hr with standard isotonic, balanced electrolyte replacement fluids.

Maintenance fluid requirements (40 mL/kg/day for larger animals and 60 mL/kg/day for smaller animals) are added to the rehydration rate. With prolonged parenteral fluid administration, usually throughout a course of days, serum sodium may increase, and maintenance fluids (eg, half-strength saline or 5% dextrose in water) may be needed to replace free water deficits.

Ongoing or increased fluid losses vary substantially and must be estimated and replaced. Ongoing losses can be estimated by measuring urine and fecal output, nasogastric tube suction, or vomitus volume. Insensible losses, which can be increased with fever, or higher metabolic demands can increase the maintenance rate by 15–20 mL/kg/day.

Monitoring Fluid Therapy

All animals receiving fluids should have a physical examination, including assessment of hydration and body weight, with urine production checked at least twice per day, more frequently in the critically ill. Overzealous administration of crystalloids can manifest as increased respiratory rate and effort, crackles or wheezes on auscultation, serous discharge from the nares, chemosis, jugular vein distention or pulsations, shivering, edema, hypertension (>140 – 150 mmHg systolic), increased CVP (>8 – 10 cm H₂O), significant increase in body weight ($>12\%$ – 15%), and rapid and/or dramatic decrease in PCV and total solids. In animals with urinary catheters, urine output can be monitored and compared with fluid administration volumes. Monitoring CVP, pulmonary capillary wedge pressures,

and cardiac output variables may be helpful in selected animals, although pulmonary artery catheters are rarely placed. Monitoring electrolytes and PCV/total solids may provide an objective measurement of fluid balance.

When parenteral fluid administration is to be discontinued, the animal should be able

to maintain hydration by voluntary drinking and eating or tolerate enteral supplementation (through a feeding tube) or subcutaneous fluid administration. Tapering the volume infused IV throughout 24–48 hr allows the renal medulla to reestablish the osmotic gradient and helps prevent excessive fluid loss through diuresis.

MONITORING THE CRITICALLY ILL ANIMAL

Anticipation, not reaction, is the key to successful management of critically ill animals. Animals must be effectively treated and actively monitored to detect or prevent organ compromise *before* organ failure occurs. This often requires aggressive and repeated fluid resuscitation and support throughout the course of definitive therapy.

Tissue hypoxia and organ compromise or failure can be a direct result of the primary disease or can be secondary to the disease or its therapy. Organs frequently affected include the heart and blood vessels, kidneys, lungs, GI tract, and liver. When the disease process is multisystemic, problems such as malnutrition and coagulopathies must be anticipated. Optimal care requires a thorough and methodical approach to diagnostic procedures, monitoring, specific therapeutics, and supportive care.

THE RULE OF 20

The Rule of 20 is a list of 20 critical parameters that should be evaluated at least daily in all critically ill animals; many of these should be assessed several times per day. Using the Rule of 20 ensures that the clinical status and therapeutic strategy for each animal is comprehensive and meets the animal's ongoing needs. Like any monitoring tool, the Rule of 20 is not a static concept but a dynamic one; the specifics of each parameter will change with advancements in laboratory testing, understanding of disease pathology, and current concepts in critical care. In addition, the systems examined in the Rule of 20 are not singularities; each is impacted by and can impact other parameters, so each parameter should be assessed while considering the patient as a whole. Some more recent applications of the Rule of 20 include monitoring of blood lactate levels, adrenal

function, body fluid glucose levels, and ultrasonographic assessment techniques. Diagnostic tools that are currently being investigated and may apply to the Rule of 20 in the future include biomarkers such as cardiac troponins, C-reactive protein, etc.

Fluid Balance: The goal of fluid therapy (see p 1675) is to provide adequate perfusion (intravascular volume) and hydration (interstitial volume) without overloading the interstitial space. Peripheral perfusion can be assessed by physical parameters such as heart rate, mucous membrane color, pulse quality, and mentation, as well as by measured parameters such as blood pressure, central venous pressure, urine output, and blood lactate measurements. Hydration can be assessed by physical parameters such as mucous membrane and corneal moistness and skin turgor, and by measured values such as body weight. Animals with systemic inflammatory response syndrome (SIRS) diseases may require more fluid than expected because of peripheral vasodilation and loss of endothelial integrity, making the administration of colloids with crystalloid solutions optimal. When treating fluid deficits, intravascular deficits should be addressed rapidly first; interstitial deficits should be treated using standard calculations to correct dehydration and monitor ongoing losses.

Oncotic Pull/Albumin: Albumin provides the major intravascular oncotic pull in the normal vasculature. In conditions in which there has been massive blood loss or leakage of plasma proteins due to an exudative process, albumin is lost from the intravascular space. This loss of intravascular oncotic pressure combined with increased capillary permeability associated

with many SIRS diseases requires treatment using synthetic colloids that have a higher molecular weight than that of albumin. Colloid oncotic pull (COP) can be measured with colloid osmometry but is not commonly available in veterinary practice. Formulas are available to calculate COP based on plasma protein levels, but they are not reliable predictors of measured COP. Normal COP in dogs is ~20 mmHg. In patients with moderate to severe decreases in COP or in total proteins, natural and synthetic colloids should be administered. Examples of natural colloids include plasma, concentrated human or canine albumin, and stroma-free hemoglobin. Examples of synthetic colloids include dextrans and hydroxyethyl starches. Newer understanding of the endothelial cell function and the impact of the endothelial glycocalyx may present novel therapeutic options in the future.

Part of the oncotic activity normally provided by albumin can be provided by synthetic colloids, but only albumin can perform other functions such as drug, cation, and hormone transport, as well as contribute to acid/base balance. Albumin can be lost with a variety of diseases (GI, renal, or SIRS); in addition, it is a negative acute-phase protein, so production of albumin drops during critical illness. Interstitial albumin stores are drawn upon to replace serum albumin, and a low serum albumin reflects a total body deficit of albumin. Albumin levels <2 g/dL have been associated with a poor prognosis; however, it is not known whether restoring albumin levels improves survival. Plasma and albumin transfusions are often administered to supplement the albumin to reach a target of 2 g/dL, but large volumes of plasma are required. Lyophilized canine serum albumin is now available in 100-g vials, making replacement of albumin more cost-effective and with lower total volumes than plasma transfusions. Human albumin products have been used in critically ill dogs but may result in severe organ dysfunction when given to healthy dogs. Interstitial albumin stores must be replenished as well as intravascular levels, so multiple units of plasma or albumin may be necessary to increase serum albumin levels.

Glucose: The goal is to maintain glucose between 80 and 120 mg/dL. Septic animals are at an increased risk of hypoglycemia that can be severe enough to cause hypotension or neurologic dysfunction ranging from weakness to stupor or seizures. Other causes of hypoglycemia

include inadequate nutrition, glycogen storage diseases, heat stroke, young age, small size, severe liver disease or portosystemic vascular anomalies, certain neoplasias, hypoadrenocorticism, and iatrogenic insulin administration. Dextrose supplementation is warranted in any animal that is hypoglycemic. Solutions with a dextrose concentration >5% are best administered through a central line. Animals with clinical hypoglycemia despite administration of solutions with high dextrose concentrations should be assessed for insulinoma and may benefit from glucagon infusions. A difference of >20 mg/dL in blood glucose values and abdominal fluid glucose values has high sensitivity and specificity for septic peritonitis in animals who have not recently had surgery.

Insulin treatment of hyperglycemia in diabetic animals is important to offset ketoacidosis or hyperosmolar complications. Constant-rate infusion (CRI) of regular insulin can result in the slow and controlled lowering of blood glucose (to help avoid rapid changes of blood osmolality); close monitoring of blood glucose levels should be performed. Tight control of increased blood glucose has improved neurologic outcome after head trauma in critical human surgical patients but not in human medical patients; in addition, increased incidences of hypoglycemia may occur with tight glucose control. Acutely traumatized animals are prone to insulin resistance because of large amounts of circulating cortisol and epinephrine and may develop hyperglycemia severe enough to require treatment with insulin. The benefit of tight blood glucose control has not been clearly demonstrated in veterinary medicine.

Electrolytes and Acid-Base Balance:

Hypokalemia can be a contributing factor in weakness and ileus of critically ill animals. These animals commonly have reduced oral intake and/or increased GI and urinary losses of potassium that require potassium supplementation in the IV fluids. Hyperkalemia can be a life-threatening complication of urinary tract rupture or obstruction, renal failure, reperfusion injury, or massive cellular death. Hyperkalemia commonly results in bradyarrhythmias and can be temporarily treated with calcium gluconate and insulin, concurrently with dextrose and/or sodium bicarbonate. The underlying pathology that led to hyperkalemia must be addressed. Other important electrolytes to monitor include sodium, ionized calcium, phosphorus, magnesium, and chloride; all

can be increased or decreased in critically ill animals and may affect other body systems (such as neurologic acid/base balance, serum osmolality, the cardiovascular system, and RBCs). The anion gap (AG) can be calculated when blood electrolytes are measured: $AG = [Na] + [K] - [HCO_3] - [Cl]$. Normal AG values are between 12 and 24 mEq/L. An increased AG indicates there is some unmeasured anion present in the blood, which may include ketones, lactate, uremic compounds, or toxins (eg, salicylates, ethylene glycol, ethanol, methanol, indomethacin, isoniazid, paraldehyde, propylene glycol). The most common cause of metabolic acidosis is lactic acidosis caused by poor perfusion leading to anaerobic metabolism. Lactate production results in an equimolar production of hydrogen ions and subsequent alterations in blood gas values (metabolic acidosis). Lactate measurements can be easily performed with handheld or benchtop analyzers. Resolution of hyperlactatemia with adequate fluid resuscitation is often associated with improved survival. Treatment involves maximizing blood flow and tissue oxygen delivery. Rarely is the administration of sodium bicarbonate ($NaHCO_3$) warranted for perfusion-related acidosis. Once perfusion and hydration are corrected, the acid-base status is reassessed.

If severe metabolic acidosis (as occurs with ketosis or uremia) persists and HCO_3 remains below ~ 12 mEq/L after perfusion has been restored, slow administration of fluids with $NaHCO_3$ supplementation is warranted, restoring serum values to >15 mEq/L. The dosage of $NaHCO_3$ is calculated as follows:

$$mEq NaHCO_3 = 0.3 \times (\text{target } NaHCO_3 [\text{eg, } 15] - \text{patient } NaHCO_3) \times \text{body weight in kg}$$

Serum bicarbonate levels are carefully monitored to meet patient requirements.

Oxygenation and Ventilation:

Pulmonary function can be compromised in critical illness for a variety of reasons (pneumonia, acute respiratory distress syndrome, thromboembolism, congestive heart failure, etc). Early diagnostic tests (eg, imaging, blood work, tracheal washes, urine blastomycosis antigen testing, etc) for targeted therapeutics will help limit extension of pulmonary disease. Aspiration pneumonia is a particular challenge, because it is most commonly a "second hit" disease (secondary to another systemic illness); therapeutics (such as antiemetics, prokinetics, or use of nasogastric tubes) to

prevent aspiration pneumonia should be used whenever appropriate. Arterial blood gas measurement is the "gold standard" method to detect hypoxemia or hypercarbia. Pulse oximetry (SpO_2) is a noninvasive way to determine the oxygen saturation of hemoglobin. Supplemental oxygen and/or therapeutic ventilation may be indicated with SpO_2 values $<96\%$. Hypercarbia can be detected using end-tidal CO_2 through an endotracheal tube or nasal catheter and has been shown to correlate with arterial CO_2 levels in animals. Serial monitoring is recommended in the initial management of animals with respiratory compromise to determine the adequacy of oxygen supplementation and the need for mechanical ventilation. If hypoxemia is unresponsive to oxygen supplementation ($PaO_2 < 60$ mmHg or $SpO_2 < 90\%$) or hypercarbia is present ($PaCO_2 > 60$ mmHg), or if respiratory effort (work of breathing) is substantially increased, manual or mechanical ventilation is necessary. Ventilation should not be delayed until respiratory failure or arrest. Prognosis for animals that require ventilation is variable; those with hypoxemia from congestive heart failure or hypoventilation from metabolic disease (eg, hypokalemia) or cervical spinal disease have a better prognosis than those that require ventilation for hypoxemia due to primary pulmonary disease. Invasive (arterial sampling) and noninvasive ($ETCO_2/SpO_2$) blood gas measurements should be performed during mechanical ventilation to determine need for adjustment of the ventilator settings.

Level of Consciousness/Mentation/Neurologic Status:

A decline in an animal's level of consciousness warrants investigation to exclude metabolic causes, such as hypoglycemia, hyperglycemia, hepatic encephalopathy, acidosis, electrolyte or osmotic derangements, or sudden development of hypertension, hypotension, or shock. An increase in intracranial pressure can result from intracranial hemorrhage, fluid overload (cerebral edema), primary brain/meningeal disease, and/or ischemia. The drugs the animal is receiving should be carefully evaluated for adverse effects that can lead to altered mentation or level of consciousness. Cerebral edema may be responsive to medical management with furosemide and concurrent mannitol therapy. Steroids may be indicated in certain inflammatory diseases (eg, meningitis, neoplasia), and antibiotics in infectious disease (eg, toxoplasmosis). Craniotomy may be needed in animals not responsive to medical

management. Cerebral perfusion pressure = mean arterial pressure – intracranial pressure. Elevating the head 15° and avoiding procedures that may increase venous pressure and subsequently intracranial pressure is essential. Maintaining normal oxygenation/ventilation, blood pressure, glucose level, and serum osmolality is essential for animals with brain disease. Neurologic status may be evaluated using a scoring system assessed on a regular basis, such as the modified Glasgow Coma Scale; lower scores are associated with a poorer prognosis.

Spinal injury that is severe enough to cause paralysis (particularly with lack of deep pain sensation) and inability to ventilate and ambulate, and that has not responded to medical management (such as anti-inflammatory medications) warrants immediate imaging and surgical intervention. Loss of deep pain is associated with a poor return to function. Serial neurologic examinations should be performed in any animal with neurologic disease.

Blood Pressure: Blood pressure should be monitored via direct or indirect methods. The goal is to maintain organ perfusion by maintaining a minimum mean arterial blood pressure >60 mmHg (systolic >90 mmHg). In hypotensive animals with adequate cardiac function, treatment consists of intravascular volume infusion (see p 1675), oxygen administration, and pain control. Hypotension unresponsive to intravascular volume replacement can be due to one or more of the following: hypoglycemia, acidosis, alkalosis, electrolyte disorders (eg, potassium, calcium, magnesium), brain-stem pathology, cardiac arrhythmias, metabolic toxins (eg, hepatic, renal), ongoing fluid loss, relative hypoadrenocorticism (eg, cortisol deficiency), heart or pericardial disease, excessive vasodilation, and excessive vasoconstriction. The need for cardiac support with positive inotropes should be assessed. An experienced ultrasonographer may be able to assess ventricular and/or capacitance vessel size to provide an estimate of preload and contractility. Once intravascular volume (central venous pressure >8 cm H₂O) and cardiac function are assessed as adequate, vasopressor therapy with CRI of dopamine (5–15 mcg/kg/min) or norepinephrine (0.05–2 mcg/kg/min), beginning at the lower end of the dosage range and increasing by increments of 0.2–0.5 mcg, is recommended. Stroma-free hemoglobin can be infused for its pressor effects.

Objective measurements of global perfusion may also include lactate monitoring; animals with a significantly increased lactate concentration may have a poorer prognosis. Studies have demonstrated that serial lactate monitoring as pathology is treated is more useful than a single measurement. Central venous oxygen measurement is another objective measurement of global perfusion; normal values are 70–80 mmHg, whereas lower values may indicate increased oxygen extraction.

Hypertension is a relatively uncommon condition in veterinary medicine, but it can lead to catastrophic problems such as retinal detachment or neurologic derangements from intracranial hemorrhage. Hypertension can exacerbate proteinuria in animals with chronic kidney disease. Moderate to severe hypertension can be treated with oral antihypertensive agents such as angiotensin-converting enzyme inhibitors (eg, benazepril), calcium channel blockers (eg, amlodipine), direct arterial dilators (eg, hydralazine), or systemic injectable antihypertensive agents such as nitroprusside (0.5–10 mcg/kg/min), titrated to effect. Blood pressure must be monitored constantly to assess response to therapy with nitroprusside. Chronic hypertension that is rapidly decreased may result in decreased renal perfusion.

The American College of Veterinary Internal Medicine classifies risk of target-organ damage from hypertension into four categories based on systolic blood pressure: I: <150 mmHg = minimal risk; II: 150–159 mmHg = mild risk; III: 160–179 mmHg = moderate risk; and IV: >180 mmHg = severe risk.

Heart Rate, Rhythm, Contractility, and Myocardial Injury: The electrical and mechanical systems of the heart should be evaluated separately. Specific antiarrhythmic drug therapy should be instituted based on an accurate ECG diagnosis when perfusion is compromised by an arrhythmia and the first-line therapy of oxygen supplementation and analgesics has been unsuccessful in controlling the arrhythmia. Arrhythmias can occur for a variety of reasons, such as SIRS diseases, splenic disease, organ torsion (eg, gastric dilatation-volvulus), and electrolyte abnormalities (eg, hyperkalemia); the underlying condition must be treated/investigated as well. Some ventricular rhythms (such as ventricular premature contractions and accelerated idioventricular arrhythmias) may not necessarily require immediate

therapy. Indications for treatment of a ventricular rhythm include tachycardia (rates >160–180 bpm), clinical signs of poor perfusion (low blood pressure, poor pulse quality, etc), multifocal arrhythmias, and R-on-T phenomenon. Other tachyarrhythmias may respond to class I, II, III, or IV antiarrhythmics; bradyarrhythmias can be challenging to treat medically and may require pacemaker placement. An echocardiogram can be performed to evaluate cardiac contractility in SIRS diseases and to detect underlying cardiac diseases. If cardiac contractility is decreased, dobutamine at 5–10 mcg/kg/min (dogs) or 2.5–5 mcg/kg/min (cats) should be considered to provide inotropic support if there is evidence of poor cardiac output. Recent studies have demonstrated that dogs with mitral valve disease and dilated cardiomyopathy have a poorer prognosis if their cardiac troponins (cTnI) and/or natriuretic peptide (NT-pro-BNP) is increased. However, these tests are not available in all hospitals and do not necessarily direct therapy, or diagnose or differentiate disease processes.

Temperature: Body temperature is considered part of the initial clinical database and should be measured regularly in every critically ill animal. A variety of diseases can result in increased or decreased body temperature. Temperature is measured most accurately and consistently with a rectal thermometer.

Increased temperatures can be seen with environmental exposure (eg, heat stroke), increased activity (eg, exercise, excitement), and infectious, inflammatory, or neoplastic diseases. Severe increases of temperature (>105.5° [40.8°C]), particularly when prolonged, can lead to severe metabolic disease such as hemorrhagic diathesis, disseminated intravascular coagulation, and SIRS diseases, which may lead to multiorgan dysfunction. Effective means of cooling animals include fluid therapy, using wet towels with fans, and placing alcohol in paw pads. Animals should not be immersed in cold water, because this causes peripheral vasoconstriction and decreases core heat dissipation. Fever of unknown origin warrants a systemic evaluation (see p 1015).

Hypothermia is most commonly associated with anesthesia in small animals; however, severe systemic disease (particularly in cats) and environmental exposure may be contributing factors. Mild hypothermia can be a common sequela of severe cardiovascular disease and is a prognostic

marker in cats with limb thromboembolism. Temperature is a vital parameter to monitor and treat in cats with clinical signs of shock, and active warming is an essential component of therapy. Therapeutic hypothermia may have some neuro-sparing effects in animals with traumatic brain injury or in postresuscitation (CPR) care; however, further investigation is needed. In animals with induced hypothermia, blood flow to most organs can be significantly decreased, and coagulation may be affected.

Altered body temperature is part of the definition of SIRS-type diseases; other parameters include an increased or decreased heart rate, increased or decreased WBC count, and an increased respiratory rate.

Coagulation: Disseminated intravascular coagulation (DIC) can develop in any animal that has undergone a period of relative vascular stasis as occurs during shock, severe tissue or capillary damage such as that which occurs with trauma, exposure of capillary endothelial cells to circulating inflammatory mediators as occurs during sepsis or SIRS, or moderate to severe alterations in body temperature. In the early stages of DIC, there may be few or no clinical signs. However, as DIC progresses, its effects are obvious and catastrophic. The goal is to detect DIC in the early stages and to slow or prevent its progression.

Early DIC is characterized by a hypercoagulable stage in which serum antithrombin (AT) levels are decreased and the coagulation cascade is activated by any of the precipitating causes. Activation of the coagulation cascade throughout the body rapidly depletes the clotting factors and the blood platelet count as platelets are incorporated into the clots. At this stage, the prothrombin time and partial thromboplastin time may be decreased, but this is a challenging stage to identify and diagnose. However, this rapidly progresses to a hypocoagulable stage as the coagulation factors are consumed. In this late stage, the prothrombin time and partial thromboplastin time (or activated clotting time) are prolonged, and fibrinogen degradation products are increased.

Treatment of DIC focuses on treating the underlying disease and removing the stimulus for continued activation of the coagulation cascade. In the early hypercoagulable stages, treatment focuses on maximizing the function of AT, which is the most abundant natural inhibitor of the serine proteases of the coagulation cascade. When AT levels are adequate, heparin can

be administered SC (50–100 U/kg, tid). If AT levels are <60% of normal, then plasma transfusions should also be given to increase the level to ≥80%. In animals with diseases known to predispose to DIC, coagulation parameters and platelet counts should be monitored. Thromboelastography (TEG) provides another means of global assessment of the clotting cascade and may be a useful tool with suspected hypo- or hypercoagulable states; hypercoagulable states are challenging to diagnose, and TEG is one of the few methods that may provide an accurate assessment.

Thrombosis occurs without DIC when there are alterations in Virchow's triad: endothelial injury, blood stasis, and hypercoagulable states. Abnormalities in one or more of these components may be seen with vascular anomalies, atrial enlargement, severe systemic illness (SIRS, immune-mediated hemolytic anemia), trauma, neoplasia, renal disease, hyperadrenocorticism, and as a primary disease in Greyhounds. The most common severe manifestations of hypercoagulability are aortic and pulmonary thromboemboli. Pulmonary thromboemboli should be suspected when significant hypoxemia is present with minimal lung changes on thoracic radiographs. Anticoagulation therapy and oxygen support should be implemented, and oxygenation and ventilation monitored. Arterial thromboembolism can occur in cats with underlying heart disease. Antithrombotics are warranted in these cases; options include aspirin and/or clopidogrel, heparin (low molecular weight or unfractionated), or warfarin. Most of these drugs require close monitoring of clotting times to achieve therapeutic goals. This disease can be painful, and opioid medications are often warranted as well as monitoring for reperfusion injury.

Disease states that result in relative hypocoagulability may include anticoagulant rodenticide ingestion, fulminant liver failure, severe thrombocytopenia, snake bites, dilutional hypocoagulability from fluid and colloid administration, and congenital defects in the coagulation cascade such as von Willebrand disease, hemophilia A or B platelet defects (Boxers), or hyperfibrinolysis (Greyhounds). Therapy should be specific to the inciting cause; plasma products are often necessary to correct life-threatening coagulopathies.

Red Blood Cell and Hemoglobin

Concentration: Because Hgb carries most of the oxygen in the blood, maintain-

ing adequate Hgb levels is essential to maintaining adequate oxygen delivery. When anemia is associated with clinical signs of tachycardia, increased respiratory rate, altered mentation, severe lethargy/weakness, and hypotension, then packed RBCs, whole blood, or stroma-free hemoglobin should be administered to bring the PCV to >20% or the Hgb level to >7 g/dL. In some cases of hemolytic or chronic anemia, the PCV can be maintained at a lower percentage before transfusion is required if there are no corresponding clinical signs. In animals that require multiple blood sampling (such as diabetic patients) or very small animals, blood sampling should be minimized to prevent iatrogenic blood loss. Optimal hemoglobin levels have not been determined; however, conservative transfusion management in people (Hgb goal of 7 g/dL or PCV of 20%) has improved survival benefit over more liberal transfusion goals (Hgb of 10 g/dL or PCV of 30%).

Except in the case of acute, life-threatening hemorrhage, before an RBC-containing blood product is administered, a crossmatch should be performed to ensure a safely administered transfusion. Even type-specific or "A-negative" blood may not be antigenically appropriate for some dogs, because many antigens are present on canine RBCs. If multiple transfusions are anticipated, blood typing should be performed as well. Only type-specific blood should be administered to cats. In dogs and cats with acute cavity (pleural or peritoneal) hemorrhage, blood may be salvaged from the cavity with aspiration (via centesis or exploratory surgery when indicated) and an autologous blood transfusion administered through a blood filter.

Rarely, disease states may result in altered hemoglobin (such as methemoglobinemia) or altered oxygen-carrying capacity (such as carboxyhemoglobinemia), often recognized by altered mucous membrane color (muddy or brick-red, respectively). Despite normal measured hemoglobin concentrations, oxygen is not being delivered to tissues in these animals, and oxygen supplementation is necessary along with treatment of the underlying disease.

An alternative means to increase oxygen-carrying capacity of the blood is a commercial stroma-free hemoglobin-based oxygen carrier (HBOC) such as Oxyglobin®. Monitoring PCV is not an adequate assessment of oxygen delivery after use of HBOCs.

Animals with a PCV >55% (other than sight hounds and at high altitudes) may

have microvascular sludging (due to the altered blood rheology) and hypertension (which impairs microvascular delivery of oxygen to the tissues). This occurs most commonly with hemorrhagic gastroenteritis. Treatment with IV fluids, and phlebotomy in cases of absolute polycythemia, are performed to improve microvascular flow and oxygen delivery to the tissues.

Renal Function: In animals that have had a hypotensive episode, are receiving potentially nephrotoxic medications, or have primary renal compromise, renal function should be evaluated daily. Urinalysis performed on a sample collected before fluid administration will help to assess renal function. Normal urine output is 1–2 mL/kg/hr and can be closely monitored with an indwelling urinary catheter. Animals in polyuric renal failure are most often managed medically; however, animals in oliguric (<0.8 mL/kg/hr), anuric (<0.03 mL/kg/hr), or relative oliguric (less than expected) renal failure may require peritoneal or hemodialysis to maintain fluid and electrolyte balance. Serial measurement of serum BUN, creatinine, electrolytes, and phosphorus will detect changes and help guide therapy. Serial urinalyses to detect glucosuria, proteinuria, or renal tubular casts help evaluate acute tubular injury before the damage progresses to overt renal failure and azotemia. If urine output monitoring with a catheter is not possible, then estimating urine output by measuring absorbent pads or litterboxes is necessary. Body weights should be recorded regularly. Additional necessary diagnostics may include urine culture and susceptibility testing, urine protein to creatinine ratio, or specific testing for renal-specific disease (eg, ethylene glycol, leptospirosis). Animals may also be monitored using a scoring system to provide additional “objective” monitoring: the International Renal Interest Society has a staging system to monitor dogs and cats with chronic renal disease based on serum creatinine, blood pressure, and proteinuria.

Infection Identification/Prevention and Treatment and Immune Status:

Strict aseptic technique should be observed when examining or treating animals that are neutropenic or receiving immunosuppressive drugs. These animals should be isolated from other animals and handled by a single person who adheres to appropriate barrier nursing techniques (washes hands, wears gloves and gown before handling the

animal, etc). All veterinary staff should be encouraged to wash hands between patients, treat wounds in a clean manner, and administer IV injections only after swabbing an IV port with an alcohol swab. Educating hospital staff on appropriate patient handling techniques may help limit development of nosocomial infections, which develop 48 hr after hospital admission.

Ultimately, antibiotic selection should be based on the results of culture and susceptibility testing, but empiric treatment, based on site of infection and suspected type of bacteria, is necessary pending these results. Empiric therapy may be based on common organisms found at the affected site and/or Gram stain and cytologic examination, which should be performed immediately. Repeat culture and susceptibility testing may be necessary in animals not responding to therapy as expected or if prolonged antibiotic therapy is anticipated.

In animals that have sustained a hypotensive episode or have a GI disease that would allow bacterial translocation, broad-spectrum bacterial coverage should be provided until the results of culture are available or the risk of systemic infection has passed.

An antibiotic protocol should be established for veterinary hospitals to minimize the number of antibiotics administered empirically on a routine basis to reduce the development of resistant organisms in the hospital environment and to improve their susceptibility patterns. Limiting use of specific classes of antibiotics or having rotating schedules may help limit development of microbial resistance. Periodic environmental cultures and facility-based monitoring of culture and facility-based monitoring of culture and susceptibility results for evidence of nosocomial infections and bacterial resistance patterns can help identify and control sources of infection and limit development of resistance. A first-generation cephalosporin (eg, cefazolin, 22 mg/kg, tid) is useful for gram-positive and gram-negative infections; an alternative choice is an aminopenicillin with a β -lactamase inhibitor (such as clavulanic acid or sulbactam), which has good gram-negative, gram-positive, and anaerobic coverage at 20–30 mg/kg, tid. If a resistant bacteria is suspected, gentamicin (3–5 mg/kg/day, IV) can be given to more specifically target gram-negative organisms after hydration and perfusion have normalized; a fluoroquinolone (eg, enrofloxacin at

5–10 mg/kg, IV, once or twice daily) is an alternative. The once-daily dosage is less likely to cause toxicity and has the same antibacterial effect as a divided dosage schedule. Metronidazole (7.5–15 mg/kg) given slowly IV over 20 min every 6–8 hr is used for suspected anaerobic infections. If multiple antibiotics are started, the antimicrobial spectrum should be narrowed and antibiotic choice adjusted as soon as the organism's susceptibility pattern is identified. Recurrent infections should be investigated for an underlying pattern of resistance, nidus of infection, or immune-compromising disease.

Newer generations and classes of antibiotics, such as carbapenems (eg, imipenim), third-generation cephalosporins (eg, ceftazidime), and vancomycin should be reserved for use in animals with bacterial infections demonstrated to be resistant to other antibiotics.

WBC counts performed on a semiregular basis (every 48–72 hr) may indicate an appropriate response to infection/inflammation or patient deterioration.

Various molecular or "bio" markers have been investigated in SIRS-type diseases to help understand and stratify disease. High mobility group box 1 protein and C-reactive protein have been associated with poor outcome or diagnosis of SIRS-type disease; however, how that information affects therapy has yet to be determined. Plasma interleukin 1B and IL-6 have been demonstrated to have some prognostic value in cats with sepsis.

GI Motility and Mucosal Integrity:

Critically ill animals, even those without a primary GI disease, are prone to gastric atony, ileus, and gastric ulceration.

Auscultation for bowel sounds should be performed three times a day. Metoclopramide (1–2 mg/kg/day as a CRI) is useful because of its central antiemetic effects and its ability to increase progressive gastric and intestinal motility. Other motility modifiers to consider include cisapride, ranitidine, and erythronycin. Motility modifiers should be avoided if gastric or intestinal obstruction is suspected or has been confirmed.

Placement of a nasogastric tube to allow removal of accumulated gas and fluid reduces the possibility of aspiration of refluxed gastric contents and allows continuous decompression. The nasogastric tube also can be used to introduce small amounts of a glucose and electrolyte solution or a liquid diet to provide nutrition directly to enterocytes,

which helps prevent gastric ulceration and intestinal mucosal compromise with secondary bacterial translocation. Antiemetics are used in animals that continue to vomit frequently despite placement of a nasogastric tube, thus improving patient comfort and reducing the incidence of aspiration, vagal-induced collapse, and bradycardia that can accompany the vomiting reflex. Metoclopramide blocks the dopaminergic receptors in the chemoreceptor trigger zone (CRTZ) and central vomiting center and acts peripherally by promoting gastric emptying. Ondansetron and dolasetron are potent antiemetics that block serotonin receptors and act at the CRTZ and the central vomiting center; they are administered at 0.6–1 mg/kg/day. Maropitant is an NK₁ receptor antagonist that blocks vomiting at the CRTZ, vomiting center, and peripheral receptors, administered at 1 mg/kg/day, SC, or 2 mg/kg/day, PO. Vomiting refractory to all other treatments in an otherwise stable animal with normal blood pressure can be treated with chlorpromazine (dogs: 0.05–1 mg/kg, IV, every 4–8 hr; cats: 0.01–0.025 mg/kg, IV, every 4–8 hr). A combination of antiemetics that have different mechanisms of action is often required to arrest refractory emesis in severe illness; in animals that require multiple antiemetics, an obstructive disease should be excluded.

GI ulceration often accompanies critical diseases such as hypotension, hypergastrinemia associated with liver and kidney disease, drug toxicities, neurologic disease, and respiratory disorders requiring ventilation. Histamine₂-receptor antagonists such as ranitidine and famotidine, and proton-pump inhibitors such as omeprazole and pantoprazole should be administered to treat gastric ulcers. However, changing the pH of the stomach can change its microbial flora. Agents such as sucralfate and barium are administered to bind to esophageal and gastric erosions and ulcers. Misoprostol may help prevent NSAID-induced ulceration when toxic levels of NSAIDs are ingested.

Drug Dosages and Metabolism: An active medications list should be kept with each animal's medical record and carefully reviewed daily for potential drug interactions, drug dosages, and possible adverse effects. If renal or hepatic function is compromised, or if protein (albumin) binding capacity is decreased, some drug

dosages should be decreased to account for altered metabolism, elimination, or protein binding. The daily review also should ensure that the dosage has been calculated correctly and that it is appropriate for the animal's current weight and body condition score. The sudden onset of any new clinical signs should be investigated in light of the medications and their potential adverse effects.

Nutrition: When nutritional needs are not met, animals rapidly develop a negative energy balance, which can result in GI dysfunction, organ dysfunction, poor wound healing, and even death. Direct enteral nutrition will improve the normal GI barrier, function, and motility. Enteral feeding is always preferred, and most animals tolerate trickle flow feeding techniques. Short-term options include syringe or forced feeding; however, this can lead to food aversion and is not comfortable for most critically ill animals. Easy to place and well-tolerated, short-term feeding tubes that allow trickle feeding include nasogastric, nasoesophageal, and nasojejunal. Nasogastric tubes also allow gastric suctioning to monitor GI function and may limit continued vomiting and risk of aspiration pneumonia; nasojejunal tubes can be challenging to place. Long-term feeding tubes include esophagostomy, pharyngostomy, gastrotomy, or jejunostomy tubes. Each of these tubes are well tolerated by most animals, and all require anesthesia to place; the esophagostomy is a minor surgical procedure, and gastrotomy tubes can be placed with endoscopic assistance.

Feeding by trickle flow is initiated with small volumes of a dilute veterinary liquid diet solution. If an animal has been starved for an extended period of time, nutrition should be increased slowly (by 25%–33% of daily caloric requirements per day) to avoid the hyperglycemia, hypokalemia, hypophosphatemia, and hypomagnesemia seen with refeeding syndrome.

For the first 12–24 hr, the diet should be calculated to provide $\frac{1}{4}$ to $\frac{1}{2}$ of the daily caloric requirement and is diluted 1 part liquid diet to 2 parts water (or electrolyte solution). This volume is delivered by CRI over 12–24 hr or divided into small boluses every 2–4 hr. Before each bolus feeding and every 6 hr during a CRI, the feeding tube should be suctioned to determine whether any residual volume is present that would necessitate decreasing the volume infused or adding prokinetic agents. After suction-

ing or administering a liquid diet, the tube should be flushed with saline. If this initial feeding is tolerated, the concentration is increased to 2 parts liquid diet mixed with 1 part water during the next 12–24 hr. If this is tolerated, then the undiluted diet can be delivered to provide the full caloric requirements. As the animal recovers, bolus feeding can be introduced by gradually decreasing feeding frequency and increasing volumes.

When nutritional needs cannot be met by enteral feeding, parenteral feeding is used. Partial parenteral nutrition, consisting of amino acid and carbohydrate solutions, can be infused through a peripheral vein, providing part of the animal's caloric requirements in a readily metabolizable form. Total parenteral nutrition (including the lipid component) must be delivered through a central venous catheter, because high osmolality of the solutions may cause phlebitis and RBC lysis. In animals with prolonged anorexia, vitamin supplementation may also be necessary.

Appetite stimulants, such as the serotonin antagonist cyproheptadine and the serotonin agonist mirtazapine, are commonly used but with varying success. Oral benzodiazepines may cause hepatotoxicity in cats and are not good alternatives; injectable benzodiazepines may be used as a short-term solution for animals with rapidly resolving disease. The use of appetite stimulants provides inconsistent food intake and is not recommended as the primary way to administer nutrition in critically ill animals.

Pain Control: Pain activates the stress hormone systems of the body and contributes to morbidity and mortality. Signs of pain are quite variable in animals; these may include decreased normal behavior (decreased appetite, ambulation, grooming, etc), development of abnormal behaviors (vocalizing, inappropriate urination, altered posture, signs of agitation or aggression, etc), reaction to touch, and altered objective physical parameters (increased heart rate, pale mucous membranes, dilated pupils, etc), which can mimic signs of shock. (See **also** SYSTEMIC PHARMACOTHERAPEUTICS OF THE NERVOUS SYSTEM, p 2590, and PAIN MANAGEMENT, p 2104.) Animals that may not show obvious signs of pain but are known to have a painful condition should receive analgesics as part of their treatment (see TABLE 7). Preemptive administration of analgesics is recommended, when possible. Pain should be assessed using a validated pain assessment tool and

monitored on a regular basis during the course of hospitalization to ensure adequate analgesia.

Analgesia in critically ill animals can safely be provided by opioids titrated to effect. Opioids provide potent analgesia (given IV, IM, or SC) with minimal

cardiovascular adverse effects, and their actions are reversible with antagonists (eg, naloxone). Long-acting opioids are best avoided in unstable animals. Reports of IV morphine causing hypotension due to histamine release do not seem to be clinically significant if the drug is given

TABLE 7 ANALGESICS USED IN EMERGENCY PRACTICE

Drug	Dosage	Comments
Morphine	Dogs: 0.05–0.4 mg/kg, IV, every 1–4 hr; 0.2–1 mg/kg, IM or SC, every 2–6 hr; 0.1 mg/kg diluted with 0.9% saline administered epidurally at 0.23 mL/kg, every 8–24 hr Cats: 0.05–0.2 mg/kg, IM or SC, every 2–6 hr	Incremental IV bolus technique: dogs—increments of 0.1 mg/kg until analgesia appears adequate; cats—increments of 0.02 mg/kg. In dogs, this can be followed by CRI at 0.1 mg/kg/hr that can be increased incrementally if needed. Rapid IV injections may cause histamine release.
Oxymorphone/hydromorphone	Dogs: 0.02–0.1 mg/kg, IV, every 2–4 hr; 0.05–0.2 mg/kg, IM or SC, every 2–6 hr Cats: 0.02–0.05 mg/kg, IV, every 2–4 hr; 0.05–0.1 mg/kg, IM or SC, every 2–6 hr	Minimal cardiovascular effects; may cause panting or emesis Can be given as a CRI with the dose divided over 4 hr
Fentanyl	Dogs: 2–10 mcg/kg, IV, every 30–60 min; 2–20 mcg/kg/hr, IV as a CRI	With short half-life, fentanyl is best administered as a CRI.
Fentanyl transdermal patch	12.5 mcg/hr for animals <2.5 kg body wt; 25 mcg/hr for animals 2.5–10 kg body wt; 50 mcg/hr for animals 10–20 kg body wt; 75 mcg/hr for animals 20–30 kg body wt; 100 mcg/hr for animals >30 kg body wt	The patches cannot be cut. More than one patch may be used in larger animals. Injectable repository fentanyl solutions may be an alternative if available.
Butorphanol	Dogs: 0.2–0.5 mg/kg, IM, IV, or SC, every 1–3 hr Cats: 0.1–0.4 mg/kg, IM, IV, or SC, every 1–6 hr	Has a ceiling effect; short duration of effect (1–2 hr) in most dogs Can be given as a CRI with the dose divided over 4 hr
Buprenorphine	Dogs: 0.005–0.02 mg/kg, IM or IV, every 1–6 hr Cats: 0.005–0.01 mg/kg, IM, IV, or sublingual, every 4–8 hr	May be more difficult to reverse Sublingual absorption reported to be excellent in cats
Methadone	0.1–0.5 mg/kg IV, IM, or SC every 4–6 hr	Less vomiting than morphine, less panting than hydromorphone

over 5–10 min or as a CRI. Other medications such as hydromorphone, oxymorphone, and fentanyl can be given without this risk. CRI provides constant analgesia and is often more convenient and less painful than intermittent IM or SC injections. In cats, injectable buprenorphine is absorbed systemically after sublingual administration. Neuroleptanalgesia can be provided by combination of an opioid with a sedative (eg, benzodiazepine) or tranquilizer (eg, acepromazine) in animals without contraindications to these medications.

For longterm control of pain, transdermal fentanyl patches or repository fentanyl injections are used but require up to 12 hr to reach therapeutic blood levels; analgesia must be provided by injection until adequate blood levels have been reached.

If pain is not adequately controlled with opioids alone, then ketamine, an NMDA receptor antagonist, can be delivered by CRI with the opioids. Ketamine may have variable effects on the cardiovascular system, making patient selection crucial, and it should not be used as a sole agent for pain relief. Lidocaine, a local anesthetic, can be used as an adjunct for systemic pain relief when delivered as a CRI and combined with ketamine and/or an opioid. Some investigation into using maropitant as an adjunctive analgesic agent is promising, because it decreased anesthetic requirements during noxious stimuli in dogs.

Local pain relief can be provided using local infiltrative or nerve blocks on extremities. Intermittent infusions of bupivacaine administered through thoracotomy tubes or abdominal catheters can provide pleural and peritoneal analgesia. Epidural injections by needle or infusions by catheter can provide pain relief from pelvic, hindlimb, and abdominal injuries or disease.

NSAIDs are rarely used in critically ill animals because of their effects on the GI tract, kidney, and liver; however, they may be appropriate in animals with significant fevers or orthopedic injury that are not systemically ill. α_2 -Agonists (such as dexmedetomidine) provide sedation as well, but case selection is critical because of the significant cardiovascular adverse effects. Other oral classes of medication that are well tolerated for mild to moderate pain include tramadol, amantidine, and gabapentin. Adjuvant methods of pain relief may include placing ice packs on regions of swelling, acupuncture, laser therapy, or massage.

Nursing Care: Providing nursing care to critically ill animals requires a skilled, knowledgeable, attentive, and highly trained nursing staff. Recumbent animals should be turned from one side to the other every 4 hr or maintained in variations of sternal recumbency to prevent decubital ulcers and atelectasis. Physical therapy 3–4 times a day is important to maintain range of motion and muscle tone and blood flow; this can be provided through massage, passive range of motion, encouraged activity, etc. Activity may also improve GI motility and provide a time when animals can urinate and defecate outside of their kennel. Catheters should be labeled and marked with the date of placement, and catheter sites should be inspected on a routine basis for signs of infection or displacement. When catheters are removed, the entrance site should be inspected for inflammation/infection. Urine and fecal soiling should be immediately cleaned. Recumbent animals require regular inspection and cleaning to prevent urine scalding of the skin; tail wraps minimize contamination from diarrhea. Nursing care must be tailored to the specific condition(s). A well-trained nursing staff can recognize deterioration or alterations in an animal often before the attending clinician because of the substantial amount of hands-on time with the patients.

Wound Care and Bandage Changes:

Bandages, essential to cover wounds, should be changed whenever they become soiled or wet. Distal limb edema can be improved by placing light compression wraps that are changed every day. (See also WOUND MANAGEMENT, p 1701.) Open wounds should be bandaged on arrival to prevent further contamination or nosocomial infection until surgical debridement can be done. Areas of skin swelling or bruising should be marked to determine progression or resolution of the pathology.

Tender, Loving Care: Owner visits should be encouraged. Animals should be handled and spoken to kindly to minimize stress and anxiety. Having familiar items such as toys or blankets from home are helpful for some pets. Consolidating several treatments at one time and turning down the lights at night, when the animal's condition permits, allow the animal some time to rest and sleep undisturbed.

OPHTHALMIC EMERGENCIES

Ophthalmic emergencies require rapid diagnosis and appropriate and often aggressive therapy for maintenance of vision.

TRAUMATIC PROPTOSIS

Traumatic proptosis may follow blunt trauma (eg, being hit by a car, fight with another animal). During trauma, the globe is luxated from the orbit, and eyelid spasms prevent its retraction. Secondary orbital hemorrhage and swelling displace the globe further from the orbit. Corneoconjunctival drying and malacia follow. Prognosis depends on pupil size and reflexes, duration of exposure, other globe or orbital damage, breed (brachycephalics are predisposed), and other systemic trauma. Approximately 40%–60% of dogs, but very few cats, recover vision. Treatment begins by providing moisture to lubricate the exposed corneoconjunctiva. General anesthesia followed by a lateral canthotomy and complete temporary tarsorrhaphy with usually two or three interrupted horizontal mattress sutures (placed at one-half thickness of the eyelids) and stents should be followed by systemic antibiotics and corticosteroids as well as topical antibiotics and mydriatics (if miosis is present). Sutures and stents are reinovied only when a brisk blink reflex returns (usually 7–21 days), or more conservatively, a single suture every 2–3 days until all have been removed. Premature suture removal results in lagophthalmia and persistent and often progressive corneal ulceration. Complications include corneal ulceration, enophthalmia, optic nerve degeneration, keratoconjunctivitis sicca, and medial rectus muscle injury.

TRAUMATIC RETROBULBAR HEMORRHAGE

Orbital and ocular contusion can produce retrobulbar hemorrhage sufficient to damage the orbital vasculature and cause exophthalmos, iridocyclitis, and lagophthalmos. This occurs most often in dogs, horses, and cats. The exophthalmos and resultant lagophthalmos are associated with an impaired blink reflex and acute exposure

Traumatic retrobulbar hemorrhage, dog; hemorrhage displaces the globe forward but not sufficiently to produce proptosis.

Courtesy of K. Gelatt.

ulcerative keratitis. Subconjunctival and intraocular hemorrhage may also be present, and the latter can prevent intraocular examination. Corneal and scleral lacerations should be excluded by ophthalmic examination, and B-scan ultrasonography to detect retinal detachment is recommended in eyes with intraocular hemorrhage.

Medical and surgical therapy consists of topical and systemic antibiotics and corticosteroids, mydriatics if pupillary dilation is necessary, and a complete temporary tarsorrhaphy to protect the cornea until a brisk blink reflex returns. Prognosis is guarded, because secondary glaucoma and phthisis bulbus are not infrequent. Intraocular hemorrhage is usually allowed to reabsorb.

EYELID LACERATIONS

Eyelid lacerations should be reapposed as soon as possible. Lacerations involving the lid margin require exact apposition to prevent longterm v-shape defects and an impaired lid function. Small dogs and cats require a single layer of sutures (usually single interrupted 4-0 silk sutures), whereas large and giant breeds require a two-layer closure; the deep layer involves the tarsus and orbicularis oculi muscle (single interrupted 4-0 absorbable sutures) and the superficial layer (skin) apposed with simple interrupted 4-0 silk sutures (remove after 7–10 days). Horses require double-layer closure. When skin sutures are in place, the

lid must be protected from self-trauma by either an Elizabethan collar (dogs and cats) or hard eye cup (horses). Because the blink response is often impaired by the swollen lid, a temporary tarsorrhaphy is necessary to protect the cornea. Postoperative therapy often includes topical antibiotics and corticosteroids, as well as systemic antibiotics and NSAIDs.

CORNEAL FOREIGN BODIES

Corneal foreign bodies are seen most frequently in dogs, cats, and horses. They are usually organic material, but sand, metal, and glass foreign bodies are also seen. Presenting signs include variable blepharospasm, tearing, and a variable secondary iridocyclitis (aqueous flare, miosis, iridal swelling, ocular hypotony, and possible hypopyon). Ophthalmic examination reveals a foreign body on the conjunctival surface, in the posterior third eyelid fornix, or on or in the cornea. Foreign bodies that adhere to the ocular surfaces are usually removed under topical anesthesia with either vigorous irrigation or small serrated ophthalmic forceps. If the foreign body has embedded within the deeper corneal layers or has penetrated into the anterior chamber, general anesthesia is required for careful removal from either the anterior corneal surface or the anterior chamber. The corneal wound is apposed with simple interrupted 7-0 to 8-0 absorbable sutures. Postoperative therapy includes topical and systemic broad-spectrum antibiotics, mydriatics, systemic NSAIDs, and if necessary, drugs to reduce intraocular pressure. Prognosis for vision is usually good. Infrequent complications include variable corneal scar formation, septic endophthalmitis, cataract formation, and secondary glaucoma.

PENETRATING INTRAOCULAR INJURIES

Penetrating intraocular injuries with retained foreign bodies are seen most frequently in dogs and cats. They are often associated with lead pellets and bullets that partially or totally traverse the ocular tunics, but splinters or spines (eg, cactus) can also cause a penetrating injury. Pellets or bullets usually cause self-sealing, slightly tan corneal defects; may cause intraocular hemorrhage; and may traverse the lens and posterior segment wall.

Perforation of the lens can lead to rapid cataract formation, especially when the anterior lens capsular tear is >2 mm long. Vitreal and retinal hemorrhage and retinal detachments are likely. Ophthalmic ultrasonography and orbital radiology are most helpful to assess pellet location and the integrity of the intraocular and orbital tissues. Anterior lens laceration and rupture is also a common sequela of cat claw injuries in young dogs.

Penetration of the anterior lens capsule (lacerations >2 mm) requires lens removal as soon as possible, because escape of lens material causes gradually intensifying lens-induced uveitis that often progresses to secondary glaucoma and phthisis bulbus. The posterior segment changes usually resolve provided the retina eventually reattaches. Focal retinal degeneration in the area of retinal penetration and detachment is common. Prognosis is guarded and based, in part, on the response to therapy and gradual clearing of the intraocular media.

Therapy is directed at controlling the post-traumatic inflammation and maintaining normal levels of intraocular pressure. Mydriatics and topical and systemic antibiotics and corticosteroids are administered to control the uveitis. Intraocular hemorrhage is allowed to resolve, with anterior chamber hemorrhage usually disappearing in ~1–2 wk and the vitreal hemorrhage resolving in 3–6 mo.

DEEP STROMAL CORNEAL ULCERS, DESCEMETOCELE, AND IRIS PROLAPSE

Most corneal ulcerations readily heal with appropriate antibiotic, antiproteinase (often topical serum), and mydriatic therapy. However, corneal ulcers detected late in the disease process, complicated by other ocular diseases, or given inadequate topical therapy can progress. These require surgical intervention using a conjunctival graft or, more recently, the commercially available porcine small-intestinal submucosa or experimental amniotic membranes. Deep corneal ulcers, descemetocele, and iris prolapse are seen with some frequency in dogs, cats, and horses. These conditions require immediate surgical support of the weakened cornea, because they can threaten or seriously compromise corneal integrity. Brachycephalic breeds and dogs with keratoconjunctivitis sicca are most

vulnerable. These corneal defects often develop in the center of the cornea and can markedly impair vision. Important diagnostic aids are the Schirmer tear test to measure aqueous tear production and topical fluorescein to determine the extent of the corneal ulcer. Corneal culture and cytology can assist in choosing topical and systemic antibiotics. Secondary anterior uveitis with aqueous flare, miosis, ocular hypotony, and hypopyon is common.

Corneal ulcer depth must be accurately estimated using magnification, focal illumination using a slit-beam, and topical fluorescein. Central corneal ulcers are more vulnerable, because they require more time for the healing response and vascularization. Adequate ulcer debridement is essential for successful adherence of a conjunctival graft. The corneal ulceration (stromal, descemetocele, or iris prolapse) is covered with the bulbar conjunctival graft (360°, 180°, bridge, or pedicle) that appears most appropriate.

For full-thickness corneal ulcers with iris prolapse, conjunctival grafts are also used, but the postoperative corneal opacity is usually larger and more dense. Postoperative therapy includes topical and systemic broad-spectrum antibiotics, systemic NSAIDs or corticosteroids, and mydriatics. Treatments are gradually tapered and administered for 4–8 wk. Postoperative complications include variable corneal scar and pigmentation, anterior and/or posterior synechiae, secondary cataract formation, and rarely bacterial endophthalmitis.

CORNEAL LACERATIONS

Corneal lacerations are seen most frequently in dogs and horses and infrequently in cats. Bites, self-inflicted trauma, and other accidents can partially or totally penetrate the cornea. Partial-thickness corneal lacerations are usually highly painful and require apposition with simple interrupted absorbable sutures to the healthy cornea. Excision of the lacerated section is not recommended.

For full-thickness corneal lacerations, signs usually include pain, blepharospasm, tearing, a corneal defect, and variable iris prolapse. Marked aqueous flare, hyphema, miosis, and distortion of the pupil are common. Often, the size of the iris prolapse is much larger than the underlying corneal laceration. Prognosis depends on size and position of the corneal laceration, other ocular tissue involvement, gender (horse), age of the animal, duration of the injury, and

other systemic injuries. If the entire eye cannot be examined directly, B-scan ultrasonography is used.

The corneal laceration is apposed with simple interrupted 7-0 to 8-0 absorbable sutures. To provide additional protection and support, the sutured laceration may be covered with a third eyelid flap, bulbar conjunctival graft, or partial temporary tarsorrhaphy. Postoperative therapy to control the secondary iridocyclitis consists of topical and systemic antibiotics, systemic NSAIDs, and mydriatics. Postoperative complications include variable and often dense corneal scarring, cataract formation with posterior synechiae, secondary glaucoma, phthisis bulbus, and bacterial endophthalmitis.

GLAUCOMA

Animals are usually presented with high-pressure glaucoma because intraocular pressure (IOP) >40–60 mmHg results in clinical signs of buphthalmia, mydriasis, corneal edema, episcleral venous congestion, and variable ocular pain. The underlying glaucoma may be either open or narrow-closed angle, and either acute or chronic. Dog breeds most often affected with primary glaucoma include the American Cocker Spaniel, Basset Hound, Chow Chow, Akita, Chinese Shar-Pei, Norwegian Elkhound, and Samoyed. In cats, glaucoma is often associated with anterior uveitis, whereas in horses the risk factors are age >10 yr old, anterior uveitis, and breed (Appaloosa). Although globe enlargement (buphthalmia) is detected fairly early in dogs, buphthalmia in horses and cats is often missed until the glaucoma has progressed.

Diagnosis depends on clinical signs and accurate tonometry. The Tono-Pen® and TonoVet® applplanation tonometers are the most versatile. Gonioscopy and other diagnostic methods are used to evaluate the anterior chamber angle and the posterior segment, including the optic nerve head.

The goals of therapy are to rapidly lower IOP and to preserve as much vision as possible. Immediate referral to a veterinary ophthalmologist is often helpful. Short-term treatment includes mannitol (1–2 g/kg, IV), topical β -blockers and carbonic anhydrase inhibitors, systemic carbonic anhydrase inhibitors, and either prostaglandin analogues or miotics (pilocarpine or demecarium). The beneficial effects of the topical medications are not usually apparent until IOP is

<30 mmHg. If mannitol treatment does not lower IOP within 2–4 hr, anterior chamber paracentesis under general anesthesia may be attempted. Longterm therapy usually includes topical and systemic ocular hypotensive medications, laser cyclophotocoagulation, cyclocryotherapy, and anterior chamber shunts.

ANTERIOR LENS LUXATION

Anterior lens luxation usually affects middle-aged dogs of the terrier breeds and is seen most frequently in Smooth and Wire Haired Fox Terriers and Jack Russell Terriers. It is associated with zonular defects in the terrier breeds (associated with the ADAMTS17 mutation), whereas in other breeds with inherited cataract formation it is associated with advanced cataract (hypermaturation) formation. These secondary glaucomas appear as acute corneal edema, increased IOP, blepharospasm, tearing, and ciliary flush. Often, the lens is in front of the pupil and often totally within the anterior chamber. Pupillary blockage with vitreous adherent to the posterior lens capsule and iridocorneal angle closure are common and can markedly increase IOP within the posterior segment. Applanation tonometry from the central cornea may yield erroneous low IOP levels. Direct examination of the posterior segment is not usually possible, and B-scan ultrasonography may be used to evaluate the vitreous and retina.

Treatment consists of lowering IOP to normal levels (usually with mannitol, 1–2 g/kg, IV); transpupillary aqueous humor flow may be reestablished with moderate dilation with 10% phenylephrine. Lens removal, preferably by phacoemulsification or intracapsular extraction, is performed as soon as possible. Postoperative treatment consists of topical and systemic antibiotics and corticosteroids and maintenance of a moderate but moving pupil. IOP is closely monitored and any increases treated with topical β -blockers, topical and systemic carbonic anhydrase inhibitors, and prostaglandin analogues. Longterm postoperative complications include anterior uveitis, secondary glaucoma, and retinal detachment.

ANTERIOR UVEITIS

(Red eye)

Anterior uveitis or iridocyclitis is most common in dogs, cats, and horses but is uncommon in other species. It is often

confused with other inflammatory conditions of the cornea and/or conjunctiva. It presents clinically as acute photophobia, pain, blepharospasm, a congested and red conjunctiva, corneal edema, reduced intraocular pressure, miosis, aqueous flare (increased levels of proteins and inflammatory cells in the aqueous humor) to frank hypopyon, and/or hyphema. Chronic anterior uveitis, in addition, may exhibit anterior and posterior synechiae, irregular pupil shape, cataract formation, and secondary glaucoma associated with peripheral anterior synechiae and/or annular posterior synechiae and iris bombé.

Anterior uveitis may be associated with trauma, systematic diseases (especially when bilateral), cataract formation, primary and metastatic neoplasia, and other causes. Prognosis and therapy depends on the cause. Therapy usually includes mydriatics, topical and systemic antibiotics, corticosteroids or NSAIDs, and other drugs to target specific pathogens. Prognosis is usually favorable for acute anterior uveitis but guarded for recurrent or chronic anterior uveitis (eg, uveodermatologic syndrome in dogs, Golden Retriever uveitis, or equine recurrent uveitis) because of the high likelihood of developing secondary cataracts, refractory glaucoma, and phthisis bulbus.

ACUTE VISION LOSS

Acute loss of vision may occur with many ophthalmic and CNS diseases, usually with abrupt onset of blindness, anisocoria, mydriasis, and loss of both direct and indirect pupillary light reflexes. Bilateral loss of vision is more common, but unilateral vision loss can occur particularly when the other eye is blind. For acute vision loss, large amounts of the retina must be involved; lesions of the optic nerve can cause blindness, because the disease process can be quite localized. The rod or cone photoreceptors may be preferentially affected initially and cause either night or day vision loss. Evaluation includes thorough ophthalmic and general physical examinations, because many systemic diseases may cause blindness. Because visual field evaluations cannot be performed in animals, subjective tests for vision are necessary and include the menace test, dazzle reflex, maze test in both light and dark illumination, electroretinography, and visual evoked potentials. See TABLES 8 and 9.

TABLE 8 CLINICAL GUIDE FOR ACUTE BLINDNESS IN DOGS

Diagnosis	Clinical Signs	Affected Visual Pathway	Etiology
Sudden acute retinal degeneration syndrome	Acute-onset blindness, dilated pupils, $\pm$ PLR ^a	Outer retinal layers	Unknown; Miniature Schnauzer and Dachshund have increased risk; increased alkaline phosphatase, ALT, and cholesterol
Optic neuritis	Acute-onset blindness, both eyes affected, dilated pupils, $\pm$ PLR	Optic nerve disc, retrobulbar	Part of systemic disease (eg, canine distemper, mycosis [cryptococcosis, blastomycosis], protothecosis, granulomatous meningoencephalomyelitis), neoplasia, trauma, orbital cellulitis
Retinal detachment	Acute blindness, hemorrhage	Neurosensory retina	Systemic hypertension, multiple intraocular myeloma
Intracranial disease	Normal eyes, acute blindness $\pm$ PLR	Optic chiasm	Pituitary masses, $\pm$ paranasal masses, meningiomas, lymphosarcoma
Central blindness	Acute blindness, normal PLR	Optic tracts, occipital cortex	Cardiac arrest during anesthesia, seizures, severe head trauma
Slow vision loss	Progressive loss of vision/PLR	Retrobulbar visual tracts	Hydrocephalus, CNS neoplasia, granulomatous meningoencephalomyelitis

^aPupillary light-induced reflexes**TABLE 9** CLINICAL GUIDE FOR ACUTE BLINDNESS IN CATS

Diagnosis	Clinical Signs	Affected Visual Pathway	Etiology
Retinal detachment	Acute blindness, hemorrhage	Neurosensory retina	Systemic hypertension, intraocular
Intracranial diseases	Normal eyes, acute blindness $\pm$ PLR ^a	Optic chiasm	Pituitary masses, $\pm$ paranasal masses, meningiomas, lymphosarcoma
Central blindness	Acute blindness, normal PLR	Optic tracts, occipital cortex	Cardiac arrest during anesthesia, seizures, severe head trauma
Slow vision loss	Progressive loss of vision/PLR	Retrobulbar visual tracts	Hydrocephalus, CNS neoplasia

^aPupillary light-induced reflexes

OPTIC NEURITIS

Optic neuritis may be divided into papillitis (an inflamed optic nerve head visible with an ophthalmoscope) and retrobulbar optic neuritis, which includes mydriasis, absence of pupillary reflexes, and blindness without any ophthalmoscopic abnormalities. Flash electroretinography, combined with visual evoked potentials, and fluorescein angiography may be used to confirm optic neuritis. A CBC, blood chemistry profile, neurologic examination, radiology, and vitreous and CSF analyses may be indicated.

Papillitis is common in 1) granulomatous meningoencephalitis in dogs; 2) systemic viral, bacterial, and fungal infections in dogs, cats, horses, and cattle; and 3) trauma. It appears as a swollen optic nerve head with blurred margins, variable hemorrhages, and exudates. Peripapillary retinitis is often present and appears as a translucent to opaque retina adjacent to the optic disk. Therapy is directed at the underlying systemic disease. Systemic corticosteroids may be used for the optic neuritis. A positive response includes return of the pupillary reflexes and normal pupil size in several days, followed by vision a few days later.

SUDDEN ACQUIRED RETINAL DEGENERATION (SARD)

SARD occurs in dogs. Clinical findings include acute loss of vision (often occurring throughout several days), widely dilated and poorly responsive to nonresponsive pupils, and a normal-appearing ocular fundus. Dogs affected most often are middle-aged and sometimes have liver disease and hyperadrenocorticism with clinical signs of weight gain, polyuria, polydipsia, and polyphagia. Electroretinography indicates loss of outer retinal

function; complete retinal and optic nerve degeneration becomes apparent ophthalmoscopically throughout several weeks. There is no effective treatment.

RETINAL DETACHMENT

Retinal detachment is being diagnosed more commonly and is an important cause of vision loss (either unilateral or bilateral). It is an important postoperative complication of cataract and lens surgery. Once retinal detachment is detected, immediate medical and/or surgical treatment can reduce the resultant retinal degeneration and facilitate restoration of vision. Contributing factors include breed (eg, Shih Tzu with vitreal syneresis), previous cataract or lens removal, trauma (dogs, horses, and cats), systemic hypertension (cats and dogs), and systemic mycoses (dogs and cats). History, complete ophthalmic and systemic examinations, CBC, blood chemistry profile, and other diagnostic tests are important to determine the underlying cause. Ophthalmoscopy, B-scan ultrasonography, electroretinography, and blood pressure measurement are important diagnostic tests for retinal detachment.

Exudative nonrhegmatogenous retinal detachments may resolve with resolution of the inflammatory or hemorrhagic intra- and subretinal exudates. Some retinal degeneration usually occurs, but vision may return. Retinal detachments secondary to Collie eye anomaly (*see* p 502) may be treated successfully by diode laser photocoagulation of the surrounding normal retina. Repair of rhegmatogenous retinal detachments, characterized by retinal breaks (holes and tears), may be attempted using vitreoretinal techniques that are routine in people, including intraocular gases, silicone oil, scleral buckling, and laser or cryoretinopexy.

WOUND MANAGEMENT

Wound healing is the restoration of the normal anatomic continuity to a disrupted area of tissue. An understanding of the normal process of wound healing is essential to make sound decisions in the management of wounds. Correctly using the principles of wound management helps avoid premature wound closure and its potential complications.

Wounds may be classified as clean, contaminated, or infected. Clean wounds are those created under aseptic conditions, eg, surgical incisions. The number of bacteria present can determine the difference between contaminated and infected wounds. As a guideline, $>10^5$ bacteria per gram of tissue is considered adequate to cause infection. The level of

contamination, blood supply, and the cause of the wound all contribute to development of the necessary conditions for infection, and each case must be assessed individually.

GENERAL PRINCIPLES OF WOUND HEALING

Although there are many types of wounds, most undergo similar stages in healing that are mediated by cytokines and other chemotactic factors within the tissue. The duration of each stage varies with the wound type, management, microbiologic, and other physiologic factors. There are three major stages of wound healing after a full-thickness skin wound.

Inflammation is the first stage of wound healing. It can be divided into several phases, resulting in the control of bleeding and the resolution of infection. During the initial phase, vasoconstriction occurs immediately to control hemorrhage, followed within minutes by vasodilation. During the second phase, cells adhere to the vascular endothelium. Within 30 min, leukocytes migrate through the vascular basement membrane into the newly created wound. Initially, neutrophils predominate (as in the peripheral blood); later, the neutrophils die off and monocytes become the predominant cell type in the wound. Debridement is the next phase of wound healing. Although neutrophils phagocytose bacteria, monocytes, rather than neutrophils, are considered essential for wound healing. After migration out of the blood vessels, monocytes are considered macrophages, which then phagocytose necrotic debris. Macrophages also attract mesenchymal cells by an undefined mechanism. Finally, mononuclear cells coalesce to form multinucleated giant cells in chronic inflammation. Lymphocytes may also be present in the wound and contribute to the immunologic response to foreign debris.

Proliferation is the second stage of wound healing. It consists of fibroblast, capillary, and epithelial proliferation phases. During the proliferation stage, mesenchymal cells transform into fibroblasts, which lay fibrin strands to act as a framework for cellular migration. In a healthy wound, fibroblasts begin to appear ~3 days after the initial injury. These fibroblasts initially secrete ground substance and later collagen. The early collagen secretion results in an initial rapid increase in wound strength, which continues to increase more slowly as the collagen fibers reorganize according to the stress on the wound.

Migrating capillaries deliver a blood supply to the wound. The center of the wound is an area of low oxygen tension that attracts capillaries following the oxygen gradient. Because of the need for oxygen, fibroblast activity depends on the rate of capillary development. As capillaries and fibroblasts proliferate, granulation tissue is produced. Because of the extensive capillary invasion, granulation tissue is both very friable and resistant to infection.

Epithelial cell migration begins within hours of the initial wound. Basal epithelial cells flatten and migrate across the open wound. The epithelial cells may slide across the defect in small groups, or "leapfrog" across one another to cover the defect. Migrating epithelial cells secrete mediators, such as transforming growth factors α and β , which enhance wound closure. Although epithelial cells migrate in random directions, migration stops when contact is made with other epithelial cells on all sides (ie, contact inhibition). Epithelial cells migrate across the open wound and can cover a properly closed surgical incision within 48 hr. In an open wound, epithelial cells must have a healthy bed of granulation tissue to cross. Epithelialization is retarded in a desiccated wound.

Remodeling is the final stage of wound healing. During this period, the newly laid collagen fibers and fibroblasts reorganize along lines of tension. Fibers in a nonfunctional orientation are replaced by functional fibers. This process allows wound strength to increase slowly over a long period (as long as 2 yr). Most wounds remain 15%–20% weaker than the original tissue. However, the urinary bladder and bone regain 100% of their original strength after wounding and repair.

INITIAL WOUND MANAGEMENT

The first step in wound management is assessment of the overall stability of the animal. Obvious open wounds can detract attention from more subtle but potentially life-threatening problems. After initial assessment, the animal should be stabilized. First aid for the wound should be performed as soon as safely possible. Active bleeding can be controlled with direct pressure. A pneumatic cuff, instead of a tourniquet, should be used in cases of severe arterial bleeding; the cuff should be inflated until hemorrhage is controlled. Use of a cuff avoids neurovascular complications that can be associated with narrow tourniquets.

Treatment for any local wound should be guided by the fundamentals of debridement, infection or inflammation control, and

moisture balance. The wound must be protected from further contamination or trauma by covering it with a sterile, lint-free dressing. The delay between examination and definitive debridement should be minimized to decrease bacterial contamination. If the wound is infected, a sample should be collected for culture and sensitivity testing. Antibiotic therapy should be instituted in all cases of dirty, infected, or puncture wounds. A broad-spectrum bactericidal antibiotic, eg, a first-generation cephalosporin, is generally recommended pending culture results. Analgesia is also indicated for pain relief.

Wound Lavage: Irrigation of the wound washes away both visible and microscopic debris. This reduces the bacterial load in the tissue, which helps decrease wound complications. Assuming the solution is nontoxic, the most important factor in wound lavage is use of large volumes to facilitate removal of debris. The recommended lavage is a moderate pressure system using a 35-mL syringe and a 19-gauge needle that delivers lavage fluid at 8 lb/sq in. The use of antibiotics in the lavage fluid is controversial.

The ideal lavage fluid would be antiseptic and nontoxic to the healing tissues. Although isotonic saline is not antiseptic, it is the least toxic to healing tissue. Surgical scrub agents should not be used because the detergent component is damaging to tissue. Dilute antiseptics can be used safely. Chlorhexidine diacetate 0.05% has sustained residual activity against a broad spectrum of bacteria while causing minimal tissue inflammation. However, gram-negative bacteria may become resistant to chlorhexidine. Stronger solutions of chlorhexidine are toxic to healing tissue. Povidone-iodine 1% is an effective antiseptic, but it has minimal residual activity and may be inactivated by purulent debris. (See also ANTISEPTICS AND DISINFECTANTS, p 2738.)

Debridement: After wound preparation and hair removal, debridement can be performed. Skin and local tissue viability should be assessed. Skin that is blue-black, leathery, thin, or white is associated with nonviability. Necrotic tissue should be sharply excised. The debridement may be done in layers or as one complete section of tissue. Tissues that have questionable viability or are associated with essential structures such as neurovascular bundles should be treated conservatively. Staged debridement may be indicated. In addition to sharp dissection, debridement may be

performed mechanically (with wet-to-dry dressings), enzymatically, or biologically (maggot therapy).

After initial inspection, lavage, and debridement, a decision must be made whether to close the wound or to manage it as an open wound. Considerations include the availability of skin for closure and the level of contamination or infection. If the wound is left open, it should be managed for optimal healing.

Wound Closure: Although **primary closure** is the simplest method of wound management, it should be used only in appropriate situations to avoid wound complications. Wounds may be closed with suture, staples, or cyanoacrylate. Clean wounds that are properly debrided usually heal without complication. With a primary closure, the layers should be individually closed to minimize "dead space" that might contribute to seroma formation. The types of suture and suture patterns used depend on the size and location of the wound and on the size of the animal.

Primary closure may not be appropriate for a grossly contaminated or infected wound. Therefore, if closure is a suitable goal, it may be delayed until the contamination or infection is controlled. The wound can be managed short-term as an open wound until it appears healthy. At that time, the wound can be safely closed with minimal risk of complications. The time between initial debridement and final closure vary according to the degree of contamination or infection. Minimally contaminated wounds may be closed after 24–72 hr. Longer periods may be required for heavily infected wounds.

Wounds that are closed >5 days after the initial wounding are considered to be **secondary closure**. This implies that granulation tissue has begun to form in the wound before closure.

Open Wound Management: When a wound cannot or should not be closed, open wound management (ie, second-intention healing) may be appropriate. Such wounds include those in which there has been a loss of skin that makes closure impossible or those that are too grossly infected to close. Longitudinal degloving injuries of the extremities are especially amenable to open wound management. Open wound management enables progressive debridement procedures and does not require specialized equipment (such as may be needed with skin grafting). However, it increases cost, prolongs time for healing, and may create complications from wound contracture.

Open wound management is based on repeated bandaging and debridement as needed until the wound heals. Traditional therapy calls for wet-to-dry dressings initially. The initial wide meshed gauze dressings help with mechanical debridement at every bandage change. Until a granulation bed forms, the bandage should be changed at least once daily. In the early stages of healing, the bandage may need to be changed as often as twice daily. After granulation tissue develops, the bandage should be changed to a dry, nonstick dressing so the granulation bed is not disrupted. Both the granulation bed and the early epithelium are easily damaged, and disruption of the granulation bed delays wound healing.

With the concept of moist wound healing, bandaging is combined with autolytic debridement to promote wound healing. The use of moist wound dressings keeps white cells healthier, allowing them to aid in the debridement process. A variety of

dressings is available. Alginate dressings are commonly used in the exudative wound to stimulate granulation tissue. Hydrogels are used to maintain moisture levels in drier wounds. Foam dressings may be used to absorb excessive exudate or protect granulation beds. These newer dressings are changed only every 2–5 days.

Sugar Dressings: Sugar has been used as an inexpensive wound dressing for more than three centuries to control odor and infection. The use of sugar is based on its high osmolality drawing fluid out of the wound and inhibiting the growth of bacteria. The use of sugar also aids in the debridement of necrotic tissue while preserving viable tissue. Granulated sugar is placed into the wound cavity in a layer 1-cm thick and covered with a thick dressing to absorb fluid drawn from the wound. The sugar dressing should be changed once daily or more frequently whenever “strike-through” is seen on the bandage. During the bandage change, the wound should be liberally lavaged with warm saline or tap water. Sugar dressings may be used until granulation tissue is seen. Once all infection is resolved, the wound may be closed or allowed to epithelialize. Because a large volume of fluid can be removed from the wound, the animal's hemodynamic and hydration status must be monitored and treated accordingly. Hypovolemia and low colloid osmotic pressure are complications that may be associated with this therapy.

Honey Dressings: Honey has also been used for wound dressings over the centuries. Honey's beneficial effects are thought to be a result of hydrogen peroxide production from activity of the glucose oxidase enzyme. The low pH of honey also may accelerate healing. Honey used for wound healing must be unpasteurized, and the source of the honey appears to be a factor in its effectiveness. Manuka honey may be the best option for wound care. The contact layer wound dressings should be soaked in honey before application. The bandages should be changed daily or more frequently as needed.

DRAINS

Drains are used to direct fluid out of a wound or body cavity. Passive drainage techniques require gravity or capillary action to draw fluid from the wound or cavity. Penrose drains are soft, flat, commonly used passive drains made from latex. These drains must be placed in

gravity-dependent locations to ensure proper function. A firmer drain can be constructed from a red rubber or silicone tube. Active drains require some type of negative pressure to pull fluid from the wound. Red rubber or silicone drains can be used with a closed system, and low-pressure suction maintained with the intermittent use of low-pressure pumps or handheld rechargeable devices. Negative-pressure wound therapy is based on this theory to remove purulent debris and speed closure of an open wound. The use of active, closed-drain systems decreases the likelihood of ascending infection that can be associated with passive drains. Drains should be left in place until the draining fluid decreases in quantity and no longer appears purulent. The fluid can be evaluated by cytologic examination.

BANDAGES

The goals of bandaging include limiting hemorrhage, immobilizing the area, preventing further trauma or contamination of the wound, preventing wound desiccation, absorbing exudate, controlling infection, and aiding in mechanical debridement of the wound. When constructing bandages, several principles must be followed to avoid complications. The bandages should be sufficiently padded, applied evenly and snugly, composed of three layers (primary, secondary, and tertiary), and placed to avoid traumatizing the newly formed granulation tissue or epithelium.

The first or primary layer directly contacts the wound to allow tissue fluid to pass through to the secondary layer. The first layer may be adherent or nonadherent. A nonadherent bandage is usually a fine mesh or foam, nonstick material and is indicated when a healthy granulation bed has developed. This layer prevents tissue desiccation and causes minimal trauma. An adherent bandage uses a wide mesh material that allows tissue and debris to become incorporated into the bandage. This debris is then removed with the bandage change. Adherent bandages are classified as dry to dry, wet to dry, or wet to wet based on the composition of the primary layer. Dry-to-dry bandages consist of dry gauze applied to the wound. The bandages are painful to remove but enable excellent tissue debridement. Wet-to-dry bandages are made with saline-moistened gauze placed directly on the wound. They are also painful to remove but result in less tissue desiccation than dry-to-dry bandages. Wet-to-wet bandages tend to damage the

tissue bed by keeping it too moist. Newer bandage materials may be impregnated with various materials, such as silver, to help control infection.

The secondary layer of a bandage absorbs tissue fluid, pads the wound, and supports or immobilizes the limb. This layer is frequently composed of cast padding or roll cotton. The tertiary layer functions to hold the primary and secondary layers in place, provide pressure, and keep the inner layers protected from the environment. This layer is composed of adhesive tape or elastic wraps.

SURGICAL TECHNIQUES

Advancement flaps can be used to move skin and relieve tension. The simplest type of advancement flap involves sliding skin to cover an adjacent defect. These flaps are elevated without regard to their vascular supply. Flap survival depends on the subdermal vascular plexus from the flap base and revascularization from the recipient bed. With subdermal plexus flaps, the vascular supply is affected by the width of the flap base. A high length/width ratio decreases the likelihood of survival, because blood supply will not reach the distal end of the flap. Any flap placed in tension carries a high risk of failure.

The basic advancement flap technique is known as the **single pedicle advancement flap**. Two slightly divergent incisions are made perpendicular to the defect. The tissue is undermined, advanced, and sutured to close the original defect. For larger wounds, two single pedicle flaps are safer than one large flap. Two advancement flaps are combined to form the "H" plasty. There are several other well-described flap techniques, including the bipedicle advancement flap and the "V-Y" advancement flap. In each of these techniques, the coverage depends on stretching the skin over the defect. For this reason, the use of these techniques may be limited by vascular supply or the regional anatomy, such as the area around the eyelids.

Flaps designed to incorporate a direct cutaneous artery are known as **axial pattern flaps** (arterial pedicle grafts). The flaps can be used to cover a large area of tissue and carry along a new blood supply to ensure flap survival. Muscle-based pattern flaps can also be used to reconstruct a body wall defect in addition to covering a loss of skin. The surviving area of axial pattern flaps is 50% greater than a corresponding subdermal plexus flap and therefore allows coverage of a larger area. Because axial pattern flaps are based on arteries, they

must have consistent landmarks and do not cover all regions of the body. The best described of the axial pattern flaps is based on the caudal superficial epigastric artery. Based in the caudal aspect of the abdominal wall, this flap can extend cranially to include mammary glands 2 through 5. Other commonly used flaps include the thoraco-dorsal, omocervical, and deep circumflex iliac artery flaps.

Free skin grafts are used for cases with massive tissue loss such as large burns or degloving injuries. The grafts are best used as a split mesh. This allows drainage and helps prevent seroma formation. Skin grafts will not remain viable if laid over squamous epithelium, denuded bone, cartilage, or tendon. The grafts must have a healthy, vascularized bed. Initially, nutrition for the flap is maintained because capillary action pulls serum into the dilated capillaries of the

skin graft, creating graft edema. Anastomosis with recipient bed vessels (inosculcation) begins within 48–72 hr of surgery. The edema may worsen immediately after inosculcation, because arterial supply is established before venous return. The edema should resolve as normal blood flow returns to the flap by day 4–6 after surgery.

All skin flaps and grafts require a clean, healthy recipient bed for survival. This is especially important for subdermal plexus flaps and free tissue transfers, because they do not contain a direct cutaneous arterial supply. The recipient bed must be free of debris, infection, and necrotic tissue.

Although flaps may have well-described anatomic markers, determining their viability may not be as easy. The simplest, but least accurate, methods to assess a flap's viability are subjective measures, including the assessment of color, warmth, sensation, and bleeding. Purple color cannot be used as a predictor of viability. Contused, purple skin is often viable. Progression from deep purple to black indicates necrosis. Skin temperature may be affected by the state of vasodilation and is therefore not an accurate method to assess viability. Viable flaps may bleed from a cut surface, as may nonviable flaps that still have some arterial function but poor or no venous return. After a flap is moved, it may develop edema for the first few days until venous vascularization is completed. Newer techniques and medications being developed for wound care include platelet-rich plasma, extracorporeal shock wave therapy, stem cell therapy, microcurrent stimulation, and a variety of growth factors. Their efficacy has not yet been completely demonstrated.

FACTORS THAT INTERFERE WITH WOUND HEALING

Factors that interfere with wound healing may be divided by source into physical, endogenous, and exogenous categories.

Physical factors that affect wound healing include temperature and mechanical forces. Temperature affects the tensile strength of wounds. Ideal conditions allow wound healing to occur at 30°C. Decreasing the temperature to 12°C results in a 20% loss of tensile wound strength. Mechanical forces include pressure and shear force. Pressure can compromise blood flow in the region, decreasing oxygen levels in the tissue. Shear forces result in tearing of the vessels. Because adequate oxygen levels are required for appropriate wound healing, anything that interferes with blood flow will

slow wound healing. Low levels of oxygen interfere with protein synthesis and fibroblast activity, causing a delay in wound healing. Oxygen levels may also be compromised by other physical factors, including hypovolemia, the presence of devitalized tissue, hematomas, and excessively tight bandages.

Endogenous factors typically reflect the overall condition of the animal. Anemia may interfere with wound healing by creating low tissue oxygen levels. Nutrition has a significant overall effect on the body. Although the ideal nutritional level for wound healing is unknown, hypoproteinemia delays wound healing when the total serum protein content is <2 g/dL. Because wound healing is a function of protein synthesis, malnutrition can alter the healing process. The addition of α -methionine or cysteine (an important amino acid in wound repair) can reverse delayed wound healing. Uremia can interfere with wound healing by slowing granulation tissue formation and inducing the synthesis of poor quality collagen. Obesity contributes to poor wound healing through decreased blood supply and with poor suture holding in the subcutaneous fat layers.

Exogenous factors include any external chemical that alters wound healing. Cortisone is commonly implicated in wound complications. Corticosteroids markedly inhibit capillary budding, fibroblast proliferation, and rate of epithelialization. Similar to cortisone, vitamin E adversely affects wound healing by slowing collagen production. Vitamin C is required for hydroxylation of proline and lysine. Zinc is required for epithelial and fibroblastic proliferation; however, excessive zinc delays wound healing by inhibiting macrophage function. Other factors that may slow wound healing include radiation, alkylating agents (eg, cyclophosphamide, melphalan), inappropriate concentrations of antiseptics, and NSAIDs. Although most NSAIDs are thought to be safe in wound healing, it has been suggested that agents selective for COX-2 inhibition may slow fracture healing.

MANAGEMENT OF SPECIFIC WOUNDS

Lacerations: Uncomplicated simple lacerations are usually managed by complete closure if they are not grossly contaminated. The wound should be thoroughly lavaged and debrided as necessary before closure. If tension is present on the wound edges, it should be relieved by tension-relieving suture techniques, sliding tissue flaps, or grafts. Deep lacerations may be treated

according to the same principles, depending on the extent of the injury. Damage to underlying structures (eg, muscles, tendons, and blood vessels) must be resolved before closure. If a laceration is grossly contaminated with debris, primary closure of the wound may not be indicated. Contaminated wounds may be closed with drains or treated as an open wound.

Bite Wounds: Bite wounds are a major cause of injuries, especially in free-ranging animals. Cat bites tend to be small, penetrating wounds that frequently become infected and must be treated as an abscess with culture, debridement, antibiotics, and drainage. Dog bites have a more varied presentation. Because of the slashing nature of dog bite injuries, the major tissue damage is usually found beneath the surface of the wound. Although only small puncture marks or bruising may be evident on the surface, ribs may be broken or internal organs seriously damaged. The animal should be thoroughly examined and stabilized before definitive wound care is begun. The wound should be surgically extended as far as necessary to allow a thorough examination and determination of its extent before a decision on the repair can be made. After a proper assessment, debridement can be performed. Unless en bloc debridement is performed, complete wound closure is usually not recommended because the sites are considered contaminated. Closure can be accomplished with drains, as a delayed closure, or by second intention depending on the extent of the injury.

Degloving Injuries: Degloving injuries result in loss of skin and a variable amount of deeper tissue. These injuries are a result of a shear force on the skin. Sources include fan belt injuries and loss of tissue during an accident with a motor vehicle. With a physiologic degloving injury, the skin is still present but completely freed from the underlying fascia. If the injury results in a loss of blood supply to the skin, necrosis may develop later. In an anatomic degloving injury, the skin is torn off the body. Degloving injuries frequently require marked and repeated debridement. Differentiating viable and nonviable tissue may be a problem in the early wound debridement process. An attempt should be made to salvage tissue in which viability is questionable. Subsequent debridement can be used to remove any necrotic tissue. With orthopedic injuries that typically accompany degloving injuries, final stabilization may be delayed until local infection is under control.

Gunshot Injuries: In gunshot injuries, most of the damage is not visible. As the projectile penetrates, it drags skin, hair, and dirt through the wound. If the projectile exits the body, the exit wound is larger than the entrance wound. The amount of damage caused by the projectile is a function of its shape, aerodynamic stability, mass, and velocity. High-velocity projectiles tend to produce more damage as a result of impact-induced shock waves that move through the tissue. The shock waves create blunt force trauma that results in tissue and vascular damage.

Gunshot wounds are always considered to be contaminated, and primary closure is generally not recommended. These wounds should be managed as open wounds or by delayed primary closure. After initial assessment and stabilization of the animal, the wound may be explored to evaluate the extent of damage and to determine a plan for repair. If the projectile caused a fracture, the method of repair depends on the location and type of fracture. External fixation, bone plates, and intramedullary nails are common choices for rigid stabilization of the

fracture so that the soft tissues may be appropriately managed. Gunshot wounds to the abdomen are an indication for exploratory celiotomy. Gunshot wounds to the thorax may require a thoracotomy if hemorrhage or pneumothorax cannot be conservatively managed.

Pressure Wounds: Pressure wounds or decubital ulcers develop as a result of pressure-induced necrosis. Pressure wounds can be extremely difficult to treat and are best prevented. Preventive measures include changing the position of the animal frequently, maintaining adequate nutrition and cleanliness, and providing a sufficiently padded bed. Factors that predispose to pressure wounds include paraplegia, tetraplegia, improper coaptation, and immobility. Mild ulcers may be managed with debridement and bandaging to prevent further trauma to the affected site. More severe wounds require extensive surgical management. After debridement and development of a granulation bed, an advancement flap or pedicle graft may be required for closure.

EQUINE EMERGENCY MEDICINE

Equine emergencies can be challenging for veterinary practitioners and emotionally charged for owners. There is also the inherent possibility of injury to the owner and veterinarian because of the sheer size of the animal and the "fight or flight" reflexes of an injured horse. Problems can be reduced by educating owners about emergency preparedness and first aid procedures. The most common types of equine emergencies are abdominal pain (colic), trauma, lacerations, and acutely ill foals.

EQUINE EMERGENCY PROCEDURES

Emergency Fluid Therapy

Conditions that may require emergency fluid replacement include injuries with concurrent blood loss, exhaustion, acute rhabdomyolysis, hyperthermia, and circulatory shock secondary to systemic illness. Fluids may be needed for maintenance purposes when oral intake is

physically not possible. Replacement fluids are required when excessive losses have been incurred or ongoing fluid losses anticipated.

Design of a fluid therapy regimen requires consideration of the volume required, the type of fluids needed, and the route and rate of administration. The volume to be administered over 24 hr can be calculated using the following formula: volume to administer (L) = maintenance rate (60 mL/kg/day) + estimated fluid deficit (body wt [kg] × estimate of dehydration) + estimate of ongoing losses. Maintenance fluid requirements are ~1 L/hr for adult horses (~450 kg) but are much lower if the animal is not eating. Dehydration can be estimated by using clinical and laboratory parameters (see TABLE 10). These numbers should be considered in relation to the horse's age and clinical condition and are only an estimate of the deficit. For example, a nervous horse may have a transiently high heart rate in response to excitement and an increased PCV because of splenic contraction.

TABLE 10

PHYSICAL AND LABORATORY PARAMETERS FOR ESTIMATION OF DEHYDRATION IN THE HORSE

Estimated Dehydration	Heart Rate (bpm)	Capillary Refill Time (sec)	PCV (%)	Total Protein (g/dL)	Plasma Creatinine (mg/dL)	Skin Elasticity (sec)	Sunken Eyes	Mucous Membrane Moisture/Color
6%	40–60	2	40	7	1.5–2	2	+/-	Moist/Pink
8%	61–80	3	45	7.5	2–3	2–3	+/-	Tacky/Pink
10%	81–100	4	50	8	3–4	3–4	+	Dry/Red
12%	>100	>4	>50	>8	>4	>4	++	Dry/Cyanotic

Ongoing losses are difficult to estimate, because losses from the GI tract are hard to measure. The equine GI tract secretes and resorbs the equivalent of the extracellular fluid volume (~30% of body wt) on a daily basis. If small-intestinal ileus or obstruction is present, the amount of gastric reflux obtained can be easily quantitated to gauge losses. If the large intestine is not resorbing water (eg, diarrhea), fluid losses can be significant but difficult to measure. With severe diarrhea, ~50% of the extracellular fluids can be lost daily.

The formula to calculate volume of fluid to administer provides only a crude estimate of needs; volumes administered should be adjusted based on responses to treatment, such as heart rate, pulse quality, capillary refill time, urine production, PCV, serum total protein, creatinine, and lactate. Reassessment is required to adjust the daily fluid requirements for any horse receiving supplemental fluids, and the timing should be dictated by the horse's clinical condition. In horses in severe shock, cardiovascular parameters may need to be monitored continually (eg, every 15 min) until improvement is noted. In horses with severe ongoing fluid losses (eg, diarrhea, anterior enteritis), cardiovascular parameters should be reassessed every 4 hr and laboratory parameters measured as frequently as 4 times a day until the horse stabilizes.

After determination of volume required, the type of fluid to be administered should be selected. Fluid choices include crystalloids (fluids containing substances that freely cross the capillary membrane) and colloids (fluids retained in the vascular space for a certain number of hours because of their larger molecular size). Crystalloids

are most commonly used for replacement fluid therapy, whereas colloids are more often reserved for resuscitation purposes. (See *also* FLUID THERAPY, p 1675.)

Two general types of crystalloids are available: balanced electrolyte solutions (BES), which are solutions of electrolytes in concentrations similar to those in plasma, and saline solutions, which contain only sodium chloride. Although considered a crystalloid, dextrose solutions are rarely used alone, and are usually added as a supplement to a BES when indicated by the needs of the individual horse. The decision to choose BES or saline can be based on a serum chemistry profile. Saline is chosen if the sodium concentration is <125 mEq/L, if there is a metabolic alkalosis, or if the potassium is >5.9 mEq/L (eg, acute hyperkalemic periodic paralysis, uroabdomen). In most emergent cases, however, a BES is used.

The addition of colloids to a fluid therapy regimen serves two purposes: it prevents edema formation caused by hypoproteinemias, and it maintains the intravascular fluid volume. Plasma products that contain antibodies to treat or prevent a variety of conditions (including endotoxemia, *Rhodococcus equi* pneumonia, West Nile virus infection, clostridial diseases, and snake envenomation) are also available. Colloid solutions are available in natural or synthetic forms. Natural colloids are plasma, serum products, or albumin. In general, fresh or fresh frozen plasma is selected when an increase in colloid oncotic pressure is needed, and coagulation factors or specific anticoagulants such as antithrombin III are indicated. Albumin solutions are not commonly administered to horses, because the intravascular half-life of albumin in diseases with

compromised vascular permeability is short. They also do not have the added benefits of whole plasma. Synthetic colloids include dextran and hydroxyethyl starch. The synthetic colloid most commonly administered to horses is hydroxyethyl starch (hetastarch). It is used to increase plasma oncotic pressure, and its effect is best evaluated by clinical response (decreased edema) or increased oncotic pressure (measured by colloid osmometry). A refractometer that measures total protein cannot be used to monitor the effect of synthetic colloid administration.

The goal of fluid therapy for treatment of shock is to rapidly expand circulating blood volume to improve tissue perfusion and oxygen delivery. Isotonic crystalloids should be administered at a dosage of up to 60–80 mL/kg in the first hour (equal to the circulating blood volume) for maximal benefit. This fluid rate, the “shock dose,” should be given in boluses of 20 mL/kg (approximately 10 L at a time), and the horse should be reassessed between each bolus to determine whether additional boluses are needed. Because of the large volumes of BES required, hypertonic fluids or colloids may be given first to immediately support the circulation until the shock dose of crystalloids can be administered. At a dosage of 2–4 mL/kg, hypertonic saline (7.5%) can rapidly expand the circulating volume by redistributing extravascular fluids into the vascular space. Because of redistribution, hypertonic solutions have a short duration of effect (~45 min) in horses. Colloid solutions can be used for a more sustained effect. Hydroxyethyl starch has been reported to increase oncotic pressure for up to 24–36 hr. However, dosages of colloids >10 mL/kg/day have caused coagulopathies. For resuscitation, a combination of hypertonic saline (4 mL/kg) and hetastarch (4 mL/kg) may have the most beneficial and sustained effects.

The flow rate of fluids through an administration set is directly proportional to the diameter of the line and inversely proportional to the viscosity of the fluid and the length of the infusion set. Polytetrafluoroethylene or polyurethane 14-gauge catheters are routinely used in horses. A rate of 7 L/hr can be achieved when fluids are >2 feet above the jugular vein, and faster rates can be achieved through gravity flow if the fluid bags are raised even higher. For more rapid flow, 10- or 12-gauge catheters with large-bore connection sets can be used, but 10-gauge catheters are more thrombogenic. Other ways to increase fluid

administration rates include cannulating both jugular veins or using a pressure bag system or peristaltic pump. Complications of peristaltic pumps are endothelial damage and an increased risk of venous thrombosis.

An alternative route of fluid administration is use of an indwelling nasogastric tube. Case selection is key, and horses that are in shock, are >8% dehydrated, or have positive net gastric reflux are not candidates for oral fluids. Equine electrolyte solutions are preferred, or a homemade mixture can be formulated using 5.27 g sodium chloride, 0.37 g potassium chloride, and 3.78 g bicarbonate per liter of water. The daily fluid rate is divided into boluses and administered using a bilge pump. The horse should be checked for reflux before administration. Volumes <8 L every 2–4 hr are typically well accepted. If a smaller gauge feeding tube is in place, a continuous delivery system from a nonsterile IV set and fluid bags or a carboy can be used, and the rate should be determined in a manner similar to that of an IV infusion rate.

Nasogastric Intubation

Nasogastric intubation is an essential and possibly life-saving procedure performed routinely in cases of equine colic to decompress the stomach and to provide therapy. After the horse is adequately restrained, the nasogastric tube is passed into the ventral meatus, using the thumb to keep the tube directed correctly. If a hard structure is encountered (eg, the ethmoid or nasal turbinates) and the tube is difficult to pass, the tube should be redirected more ventrally. Once the pharynx is reached, a soft resistance is felt when the tube contacts the larynx and/or esophageal opening. The horse's head is flexed at the poll, and the tube can be turned 180° so that the curvature of the tube is directed dorsally toward the esophagus. Swallowing is stimulated with gentle pressure against the esophageal opening or by blowing small puffs of air into the tube, and the tube is then passed into the esophagus by coordinating with the swallow reflex.

Once the tube is in the esophagus, mouth suction on the tube will be met with negative resistance. The tube may also be palpated in the proper position dorsal to the larynx or on the left side of the neck above the jugular vein. If the tube is in the trachea, shaking the trachea will result in a “rattle.” If the horse coughs, or if air is noted when suction is applied by mouth, the tube should be withdrawn into the pharynx and the procedure repeated until the tube is

correctly positioned. Once the tube is confirmed in the esophagus, intermittently blowing into the tube will help to dilate the esophagus and facilitate insertion into the stomach. The tube is advanced into the stomach until level with the twelfth rib. If difficulty is encountered in passing the tube through the cardia, 60 mL of mepivacaine may be injected into the tube and followed with air or water.

Once the tube is in place, if there is no spontaneous reflux, the stomach should be lavaged. It should not be assumed that any excess fluid in the stomach will drain spontaneously. Medications should never be administered by nasogastric tube without checking first for net reflux. To do so, the tube is filled with ~2 L of water using a pump or funnel with gravity flow to establish a siphon effect, the pump removed, and the end of the tube directed downward to verify the presence of gastric contents. Subtracting the amount of water pumped in from the amount of fluid obtained determines the "net" reflux. Horses should be lavaged with at least 8 L of water to confirm lack of net reflux before any therapy is administered.

Net nasogastric reflux is not normal. Occasionally, a small amount of reflux (<1 L) is obtained if a horse has had an indwelling nasogastric tube. In most horses with colic, >2 L net reflux is abnormal. When reflux is obtained, the amount, character, and timing in relation to the onset of colic should be noted, as well as any clinical response to gastric decompression.

Typically, reflux accompanies small-intestinal ileus, either functional or mechanical. Lesions of the proximal small intestine or pylorus produce large amounts of reflux early in relation to the onset of colic. With lesions of the distal jejunum and ileum, there is initially no reflux, but nasogastric reflux usually becomes productive several hours after the onset of colic. Occasionally, large-colon disorders can be associated with net reflux if the colonic distention exerts pressure on the duodenum as it courses over the base of the cecum. Foul-smelling, fermented, or copious bloody reflux is associated with anterior enteritis and should be treated as a biohazard because of the association of this disease with clostridial and *Salmonella* spp organisms. With mechanical obstruction, including strangulating lesions and ileal impactions, the reflux is usually composed of fresh feed material and intestinal secretions. Reflux originating from the small intestine is alkaline, whereas reflux composed of gastric secretions is acidic.

Because gastric outflow obstruction is rare in horses, pH is usually not measured.

Response to gastric decompression should be noted. Horses with functional ileus show signs of relief, and the heart rate may decrease in response to decompression. Horses with a mechanical obstruction usually remain in pain, although some do respond. The rest of the physical examination of horses with reflux should focus on determining whether functional or mechanical ileus is present. The amount of reflux obtained should be noted after each decompression, and the volume of fluids given IV adjusted accordingly. Horses with functional ileus generally need gastric decompression every 2–4 hr. The nasogastric tube should be left in place only as long as required, because it can cause pharyngeal and laryngeal irritation. Esophageal rupture has been described in severe cases.

Abdominocentesis

Abdominocentesis is important in the evaluation of abdominal disease (eg, weight loss, colic, peritoneal effusions, or postoperative complications). Ultrasonography can be used to determine the best location to obtain a fluid sample, which can be collected using an 18-gauge needle, a catheter, or a teat cannula through a stab incision. Most commonly, the sample is obtained just to the right of midline, caudal to the descending pectoral muscle on the dependent abdomen. This will prevent the site of the abdominocentesis from interfering with a surgical incision if an exploratory laparotomy is needed, and it will also help to avoid the spleen. The body wall is much thicker off midline, and the length of the instrument used to sample the fluid should be considered. A needle tap should be avoided with severe small-intestinal distention to reduce the risk of bowel puncture and iatrogenic peritonitis. The fluid is collected using sterile technique and placed in a tube with anticoagulant for analysis and in a culture tube if peritonitis is suspected. It is useful to shake out the EDTA from the tube before sampling, because EDTA will falsely increase the total protein.

Normal values for abdominocentesis include a total protein <2.5 g/dL and WBC counts of <5,000 cells/ μ L. Repeated abdominocentesis will not significantly alter these values above reference ranges. On cytology, neutrophils comprise most of the cells; the remainder are lymphocytes, macrophages, and peritoneal cells. With intestinal strangulation, protein increases in

the first 1–2 hr. After 3–4 hr of strangulation, RBCs are present, and after ≥6 hr, WBCs increase gradually as intestinal necrosis progresses. Degenerate neutrophils will be noted on cytology, and the gross appearance is serosanguinous. Peritoneal lactate is also increased with intestinal ischemia (>4 mmol/L) or is found to increase over time if serial abdominocentesis are performed.

Enterocentesis sometimes occurs, especially in cases of sand colic, and should be differentiated from intestinal rupture. With enterocentesis, cytology reveals plant material, bacteria, and debris but few cells. The horse's clinical condition is not consistent with rupture, although in early rupture (~2–4 hr), clinical signs of endotoxemia (eg, depression, tachycardia, congested mucous membranes, shock) may not be seen. Cytology of abdominal fluid compatible with intestinal rupture shows a large number of toxic and degenerate neutrophils, in addition to bacterial organisms, plant material, and bacteria that have been phagocytized by neutrophils.

Blood contamination that occurs during the procedure should be differentiated from internal hemorrhage or severely devitalized bowel. Blood from skin vessels or an abdominal vessel usually swirls in the sample and spins down when centrifuged, leaving the sample clear. Fresh blood contamination shows platelets, which are not present in blood >12 hr old. If the spleen is accidentally punctured, centrifugation of the sample reveals a PCV the same or higher than the peripheral PCV. In internal hemorrhage, the blood in the sample is hemolyzed, there are no platelets, and erythrophagocytosis may be seen. When centrifuged, the supernatant will remain reddish. Abdominal ultrasound will reveal fluid swirling on the abdomen. If vascular compromise of the bowel occurs, hemolysis of RBCs that leak from damaged capillaries will result in a serosanguineous fluid, with a red supernatant after a spin.

Abdominal surgery increases the total protein and WBCs in the abdominocentesis. With a sterile peritonitis, the WBC count will remain increased for up to 2 wk, and cell counts of 40,000 cells/dL have been reported at 6 days after surgery. Neutrophils will appear nondegenerate on cytology, and there are no bacteria. The total protein peaks at 6 g/dL 6 days after surgery and may remain increased for 1 mo. After an enterotomy, or resection and anastomosis, degenerate neutrophils and occasional bacteria may be seen in the first 12–24 hr but should resolve in time. If septic peritonitis is present, clinical signs will be consistent

with bacterial infection (eg, fever, depression, anorexia, ileus, colic, endotoxemia). The WBC and total protein in the abdominocentesis will be markedly increased. On cytology, >90% of cells are neutrophils and will appear degenerate. Free and phagocytized bacteria are seen. A serum–peritoneal glucose difference >50 mg/dL or a peritoneal fluid pH <7.2 with a peritoneal glucose <30 mg/dL is supportive of a diagnosis of peritonitis.

Trocarization

Trocarization is useful to decompress the abdomen when abdominal compartment syndrome is suspected (increased intra-abdominal pressure resulting in severe abdominal distention, dyspnea, and perfusion abnormalities). Trocarization is performed only for distention of the cecum and large intestine, and never to decompress the small intestine or stomach. Thus, it is necessary to identify the segment of intestine involved before the procedure. In adult horses, this is done by transrectal palpation combined with transabdominal ultrasound. Abdominal auscultation may note a “ping” after percussion indicative of a gas-filled organ. In foals or small horses, radiographs and/or ultrasound can be used. The distended segment of large intestine must also be against the body wall so it can be safely reached. The most common site for trocarization is the upper right flank, just cranial to the greater trochanter at the location of the cecal base. Ultrasound is used to confirm a gas-filled structure at the chosen site, to avoid other organs or large blood vessels.

In adult horses, a 14-gauge, 12.5-cm over-the-needle catheter is typically used, whereas in neonates, a 5-cm needle may be adequate. The area is clipped, sterilely prepared, and infiltrated with a local anesthetic. The catheter is inserted aseptically and attached to a long extension set that is placed in a nonsterile cup of water to monitor progress. Gas released will produce bubbles, and the catheter may be repositioned as the bowel decompresses. A successful trocarization may take >30 min to decompress the bowel. When removing the catheter, an antibiotic (usually ~5 mL of gentamicin) is infused as the catheter is withdrawn.

Complications after trocarization include peritonitis, hemorrhage, and a local subcutaneous abscess. The horse should be observed for 48 hr for signs of peritonitis, including abdominal pain and fever. Peritonitis is confirmed with abdominocentesis and treated with systemic broad-spectrum

antibiotics until it is resolved. Hemorrhage is typically self-limiting, and local abscesses can be drained percutaneously.

Tracheostomy

Tracheostomy is used as an emergency procedure for conditions resulting in acute upper airway obstruction (eg, arytenoid chondritis, snakebite). The incision site is selected at the junction of the proximal and middle third of the neck, above the "V" formed by the paired sternomandibularis muscles. If possible, the skin should be clipped, aseptically prepared, and infiltrated with a local anesthetic. In acute respiratory distress, this may not be possible, and the procedure is performed without sterile preparation.

The incision (6–8 cm) is made on midline, through the skin and between the paired sternothyrohyoid muscles. The trachea is exposed, and a transverse incision is made between two tracheal rings, taking care to avoid the tracheal cartilages. The incision will extend to ~30% of the circumference of the trachea. If the horse's head is elevated or extended, the tracheal incision should be made caudal relative to the skin incision, to avoid covering the tracheostomy site when the head is lowered. A J-type silicone tracheostomy tube may be used and secured in place to the mane with gauze. The cuff should not be inflated, unless the horse is to be ventilated, to prevent tracheal necrosis. Alternatively, a self-retaining tube may be preferred because of the tendency of J-tubes to fall out.

The tracheostomy tube should be removed, cleaned, and replaced twice a day or more often if secretions occlude the lumen. Petroleum jelly applied to the surrounding skin will help to reduce skin scalding. Complications are rare (eg, cartilage deformity, intraluminal granulation tissue, mucosal structure) but can be reduced by removing the tube as soon as possible. One method to determine when the tube can be removed is to temporarily occlude the lumen by hand and observe whether the horse can breathe without it. After tube removal, the site is cleaned with saline twice daily and allowed to heal by second intention. The trachea will generally close in 10–14 days and heal completely in 3 wk.

EQUINE TRAUMA AND FIRST AID

Common emergencies involving the musculoskeletal system include fractures, luxations, lacerations, puncture wounds,

synovial infections, and exertional rhabdomyolysis. Although many of these conditions cannot be treated in the field, an accurate diagnosis and provision of appropriate emergency treatment are essential for the possibility of a successful outcome.

Fractures and Luxations

A thorough physical examination is warranted but may be complicated by the severity of the injury and other factors (eg, pain, anxiety, exhaustion, dehydration, owner/trainer anxiety). The goals of initial coaptation of fractures are to relieve anxiety, prevent further injury, and allow for safe transportation for additional evaluation and possible treatment. Emergency coaptation of unstable limbs is key and should be performed before radiographic evaluation or transportation to a surgical facility.

Initial Assessment: Fractures or luxations should be suspected if a loud crack is heard, if there is acute, non-weight-bearing lameness, or if the limb has an abnormal angulation or is visibly unstable. The extent of the physical examination should be dictated by the situation, to avoid further injury to the horse or bystanders. If the horse is recumbent, full assessment of the limb should be completed before attempting to stand the horse. If the horse is standing, examination of the limb should be completed before attempting to move the horse. With an unstable fracture, the limb should be stabilized before any other treatment.

Sedation or a twitch can be used to aid restraint for the examination. For sedation, an α_2 -agonist such as xylazine or detomidine can be used. Because α_2 -agonists often cause the horse to lean forward, which may increase the weight on an injured forelimb or decrease the ability to manipulate the limb, the minimal effective dose is preferred to reduce ataxia. However, up to double the standard dose regimen may be required to achieve effective sedation after maximal exercise or if the horse is excited. Butorphanol may be used for horses not well controlled by α_2 -agonists alone. Acepromazine should be reserved for euvoletic horses because of its hypotensive effects. If the horse is recumbent and a serious injury is suspected, general anesthesia can be safely induced using sedation with xylazine followed by induction with ketamine and diazepam or tiletamine-zolazepam. Before sedation or anesthesia, the circulatory

system should be briefly assessed by evaluating heart rate, mucous membrane color, capillary refill time, and pulse quality. A heart rate >80 bpm accompanied by a delayed capillary refill time and poor peripheral pulse quality indicate the need for IV fluid support. Laboratory determination of biochemistry profile indices are becoming more commonly available in field situations. If available, parameters of hydration and electrolyte balance are useful to dictate fluid volume and type.

For limb stabilization, it is useful to divide the limbs into four levels, which help define the method of coaptation. Level 1 injuries involve the distal metacarpus/metatarsus and phalanges and include the fetlock joint and extensor and flexor tendon injuries located at the level of the metacarpus and metatarsus. Level 2 injuries involve the mid-metacarpus to distal radius, the carpal joint, and the mid- to proximal metatarsus. Level 3 injuries involve the mid- to proximal radius in the forelimb or the tarsus and tibia in the hindlimb. Level 4 injuries are noted in the forelimb proximal to and including the elbow joint, or in the hindlimb proximal to and including the stifle joint.

The presence of a fracture can be determined by instability, crepitus, abnormal angulation, palpation of bone fragments, or direct visualization of the fractured bone. Luxation should be suspected when there is abnormal lateral-to-medial motion at the level of a joint. Radiographs are indicated to confirm the presence or absence of a fracture or luxation but only after coaptation has been applied. If radiographic equipment is unavailable on site, the horse should be transported to a referral facility for further examination. Hairline or stress fractures can be difficult to demonstrate radiographically, particularly in field conditions. Therefore, in the presence of severe lameness with pain localized to a long bone, external coaptation should be applied before moving the horse, to avoid catastrophic displacement of an incomplete fracture.

Emergency Treatment: Therapeutic aims of the initial management of traumatic injuries are to relieve anxiety, immobilize the fracture or luxation for transportation, prevent further damage, and provide safe transportation. The principles of emergency coaptation of traumatic injuries in horses include appropriate wound care before application of external coaptation, provision of adequate padding to prevent skin abrasions, immobilization of the joint

below and above the area of injury, prevention of lateromedial and craniocaudal motion, and never ending a splint in the middle of a long bone segment or at the end of a fracture line.

Wounds should be carefully cleaned and debrided. A nonstick gauze bandage can be applied and held in place with conforming gauze. Cotton padding is applied to the entire length of the segment to be immobilized and held in place with gauze, followed by elastic bandage material. The bandage should be snug, to avoid loosening with compression of the cotton material. Splints are then applied and held in place, ideally with fiberglass casting tape. This is particularly useful in stabilizing a luxation. If casting tape is unavailable, heavy tape (duct tape or medical white tape) can be used. The splints must be well padded to avoid the development of sores.

Immobilization of Level 1 Injuries:

Level 1 injuries include phalangeal fractures, distal metacarpus and metatarsal fractures, sesamoid fractures, fetlock, pastern or coffin bone luxations, or severance of one or more flexor tendons. Not included are fractures of the coffin bone; they are supported by the hoof capsule and do not require a splint. Although technically level 1 injuries, extensor tendon lacerations require a different mode of splint application and are discussed separately.

Forelimb and hindlimb immobilization differ slightly because of the presence of the reciprocal apparatus in the hindlimb. In forelimb injuries, immobilization is best accomplished by aligning the cannon bone with the phalanges to establish a straight, weight-bearing column. The horse will bear weight, although not fully weight bearing, on its toe. To bandage the limb, an assistant holds the leg by the radius, allowing the limb distal to the carpus to hang in a straight line to facilitate bandaging. A modified Robert-Jones bandage is placed using cotton combine bandage, brown gauze, and elastic bandaging material to form a light bandage that will allow for soft-tissue swelling. Each layer of bandaging material is wrapped separately and in the same direction to prevent shifting of the splint. A splint is applied to the cranial aspect of the limb, extending from toe to carpus using 4–6 layers of overlapping, nonelastic tape (eg, white medical tape, duct tape). The splint should be padded proximally to prevent skin injury. If lateral to medial instability is noted, a lateral splint may be added or casting tape applied over the splint.

In the hindlimb, the reciprocal apparatus prevents extension of the distal limb if the horse is non-weightbearing. Therefore, the limb is best immobilized by applying the splint on the caudal aspect of the limb, from the toe, on the plantar aspect of the hoof, to the point of the hock. Dorsal alignment of the bony column will not be possible and is not necessary for adequate coaptation. Bandaging and splinting techniques are otherwise similar to those used for the forelimb.

A commercially available splint (Kimsey Legsaver®) may be used for some level 1 fractures or tendon injuries; however, it does not provide enough lateral-to-medial stability for joint luxations or severely comminuted fractures. The splint is readily available in a number of sizes, easy to apply, and effective to achieve immediate immobilization. Two configurations are available: one with a slightly forward-angled bar for a flexed position of the forelimb, and one with a backward angle at the level of the fetlock to improve weight bearing. The forward angle is more effective for most fore- and hindlimb injuries, when weight bearing is not advantageous. Nonslip tape should be placed on the foot plate after application to make it less slippery, particularly on cement floors.

Lacerations or rupture of the extensor tendons, unlike flexor tendons, require a different type of splint. When both extensor tendons are completely disrupted, the horse will knuckle over, which can lead to injury of the dorsal aspect of the fetlock and further disrupt any associated wound. In this instance, external coaptation is needed to prevent knuckling over at the fetlock. A splint is applied to the cranial aspect of the fore- or hindlimb with the hoof flat on the ground to prevent joint flexion.

Immobilization of Level 2 Injuries:

Examples of level 2 injuries include mid to proximal cannon bone fractures, carpal bone fractures, distal radial fractures, and wounds of the carpus. The goal of coaptation is to prevent angulation and place the carpus in extension. In level 2 injuries of the forelimb, a moderately thick Robert Jones bandage is applied up to the elbow, wrapping each layer separately to prevent slipping. The bandage should be ~3 times the diameter of the limb when finished, so that the entire splint lies flat against the bandage over its length. Two splints are applied, at a 90° angle, one lateral and one caudal. The splints should extend from the floor to the elbow, and the hoof should be flat on the floor. In hindlimb

injuries, as in the forelimb, the bandage should be 3 times the diameter of the limb and extend from the floor to the stifle. Two splints are needed. One splint will extend from the floor to the stifle laterally. However, because of interference with the reciprocal apparatus and the angulation of the hock, the caudal splint cannot extend to the stifle but should stop at the point of the hock.

Immobilization of Level 3 Injuries:

Level 3 injuries include fractures of the mid to proximal radius, tarsus, or tibia. Because of the nature of the fracture, the flexor muscles of the limb become abductors, resulting in a valgus angulation. The medial aspect of both the radius and tibia does not have a sufficient muscle mass to help prevent penetration of the skin by fractured bone, and open fractures are common. The goal of external coaptation is to prevent abduction of the limb and soft-tissue injury. On the forelimb, the splint is applied similar to that in level 2 injuries; however, the lateral splint must extend from the ground to the withers. The caudal splint is the same, extending up to the elbow. The lateral splint above the bandage should be well padded to improve fit and prevent skin injury. Once the horse is standing on the trailer, the splint can be secured to the chest with nonelastic tape in a figure-8 configuration for further stability, if needed. On the hindlimb, the splint is similar to that for a level 2 injury; however, the caudal splint is not needed, and the lateral splint should extend to the level of the tuber coxae. The splint can be a wide wooden board or a contoured metal splint made of electrical conduit. Adequate padding should be placed wherever the splint contacts skin above the bandage. Placing the hoof in extension can facilitate splint application.

Immobilization of Level 4 Injuries:

Level 4 injuries include fractures of the scapula, humerus, femur, and pelvis. They also include olecranon fractures and radial nerve paralysis because these injuries disrupt the passive stay apparatus in the forelimb. The flexion of the carpus that results can cause injury to the dorsal aspect of the limb and eventually tendon contraction. For forelimb fractures and radial nerve paralysis, a level 2 bandage and a caudal splint from the ground to the elbow is used to fix the carpus in extension. Although the fracture is not directly stabilized by this splint, it will prevent tendon contraction and allows the horse to prop the leg, which reduces anxiety. External coaptation is not

indicated for fractures of the hindlimb at this level. The joint above and below the fracture cannot be immobilized, preventing fracture stabilization. Bandaging will only distract the fracture and make it more awkward to move the horse. Hematoma and soft-tissue swelling around the site of injury will provide functional immobilization. If the pelvis is fractured, the need for transportation and further diagnostics should be discussed, because motion during transit may displace fracture fragments, resulting in fatal hemorrhage.

Guidelines for Safe Transportation

Before loading an injured horse, proper functioning of the vehicle should be assessed, the horse stabilized, and the injury immobilized as described. A low ramp facilitates loading and unloading. The trailer ideally should be brought to the horse if possible for loading. Once loaded in the trailer, the horse will lean on the wall and partitions to help balance and to reduce the load on the injured leg. It is never advised to transport a horse loose in a trailer or in a makeshift stall. A sling can be placed under the abdomen to help reduce the weight bearing on the limb. Many trailers have standing stalls at 45° angles (slant load trailers), which help horses balance during transport. If a regular, straight-load trailer is used, the horse should be loaded facing backward for a forelimb injury and forward for a hindlimb injury, to help cushion sudden stops. The head should be loosely tied, in case the horse falls, and a hay net provided to reduce anxiety. Frequent stops should be made to check on the status of the horse and provide drinking water. If significant cardiovascular compromise exists, IV fluids can be administered while in transit.

If the horse is severely injured and needs to remain recumbent, it can be pulled onto the trailer after stabilizing the limb using a large tarp or blankets as a glide. The horse should be kept sedated during transport to avoid further injuries. A head protector, hay bales, or a bandage can be used to protect the head from self-trauma, and the down eye should be padded with a towel or blanket. The halter should be padded or removed to reduce the risk of facial nerve paralysis, with lower limb bandages applied to the remaining limbs to avoid trauma caused by paddling. Foals can be transported in recumbency with the help of restraint by a handler either in a trailer with the mare or separated from the mare in the vehicle with a handler.

Wounds and Lacerations

Wounds and lacerations are common in horses. The steps involved in management of these injuries include control of hemorrhage, identification of all involved structures, and evaluation of the need for referral. Referral to a surgical facility is recommended if there are tendon injuries, penetration of a synovial structure, extensive degloving injury, severe blood loss, neurologic signs, or involvement of the thoracic or abdominal cavity. In addition to wound management, tetanus prophylaxis, analgesia, and appropriate antimicrobial therapy are indicated. If severe blood loss has occurred, cardiovascular support should be provided before and/or during transportation.

Assessment: A brief physical examination should be completed before addressing the primary problem. If the wound is located on the limb, the presence and degree of lameness should be noted as indicators of a potentially more serious injury and the need for coaptation. The following characteristics are then evaluated: location, hemorrhage, configuration, penetration of a body cavity or synovial structure, and/or involvement of tendons. Assessment should first include application of a sterile, water-based lubricant, clipping of the hair, sterile preparation of the skin, and lavage of the wound. Wounds over joints, tendon sheaths, or tendons (particularly flexor tendons), puncture wounds, and those that expose or penetrate bone should be explored thoroughly for injury to important underlying structures. Hemorrhage may need to be controlled before further wound assessment is possible. Pressure bandages may be applied, and if the vessel can be located, it should be temporarily clamped or ligated. Certain wound configurations may significantly damage the blood supply to the skin and subcutaneous tissues and result in sloughing (eg, an inverted "V" configuration, crushing injuries with significant bruising). Wounds over the chest or abdomen may penetrate important organs. In the case of thoracic wounds, development of an open or closed pneumothorax can lead to severe respiratory distress. Any horse with chest trauma and dyspnea should have all open wounds sealed with plastic, airtight bandages and evaluated for a pneumothorax.

The potential involvement of a synovial structure should be immediately determined. The horse should be restrained and sedated as needed for the procedure. A site of entry into the joint or tendon sheath

remote from the wound is chosen, clipped, and aseptically prepared. Using sterile technique, saline or a balanced electrolyte solution is injected into the synovial compartment. The amount needed to achieve distention and back-pressure can vary from a few milliliters, in the case of the distal tarsal joints, to >100 mL for the femoropatellar joint. All compartments of the joint should be assessed. Synovial structure involvement may be confirmed if leakage of the injected solution is noted from the wound. If communication is not noted, the solution is aspirated from the joint, and the structure is injected with a prophylactic dose of an antibiotic (eg, amikacin). In chronic wounds or injuries caused by a puncture, the communication with the synovial cavity may have sealed. Horses should be reevaluated for increased lameness, heat, or effusion over the next 3–5 days, which could be evidence of an insidious infection. If there is significant edema, swelling, or skin trauma over all points of entry, the synovial structure should not be tapped to avoid the possibility of iatrogenic infection. In these cases, close monitoring or direct probing of the wound with a sterile instrument and radiographic assessment may be diagnostic.

Extensor tendon injury of the distal limbs results in the inability to appropriately place the hoof on the ground, and knuckling over. This suggests involvement of both extensor tendons in the proximal metacarpus or metatarsus, or the common digital extensor tendon more distally. Flexor tendon injuries result in hyperextension of the fetlock (superficial digital flexor), lifting of the toe (deep digital flexor), or complete dropping of the fetlock to the ground (severance or rupture of the suspensory ligament). For this to be seen, the horse must bear weight on the limb at least transiently, but this is not advised. In complete suspensory breakdown, severe stretching of the digital vessels can lead to thrombosis and avascular injury and necrosis of the distal limb. It is important to support the fetlock and not allow weight bearing until the limb is stabilized in a flexed position.

The goals of initial wound care are to decontaminate the wound as much as possible and prevent further contamination during transportation. After clipping and sterile preparation of the intact skin, the injured tissue is lavaged with sterile saline and cleaned by sharp debridement of gross contamination. The wound should be dressed with a sterile, nonstick bandage and a support wrap or padded bandage. Immobilization of the limb (*see p 1714*) will

be needed if there is injury to a supporting structure (bone, tendon) or significant instability (luxation).

Pneumothorax: A penetrating chest wound can result in development of a pneumothorax and lead to respiratory distress. If untreated, pneumomediastinum can result, and this or the primary pneumothorax can be fatal. On examination, a restrictive pattern to the respirations is noted. Auscultation of the thorax will reveal a lack of breath sounds in the dorsal lung fields. Because of the incomplete mediastinum in horses, a unilateral chest wound can lead to bilateral pneumothorax. An open pneumothorax is managed by providing a temporary seal over the chest wound. The wound is cleansed and bandaged with a layer of airtight plastic wrap and sealed with elastic adhesive tape. The chest is then evacuated by inserting a 14-gauge catheter, using aseptic technique, in the dorsal aspect of the 12th intercostal space. Aspiration can be facilitated by use of a 3-way stopcock and 60-mL syringe or by negative suction. A closed pneumothorax may require an indwelling chest tube and Heimlich valve until the cause is resolved.

Hemothorax: Hemothorax is a possible complication of a penetrating chest wound and can lead to respiratory distress similar to that seen in pneumothorax. Auscultation of the thorax will reveal a lack of breath sounds in the ventral lung fields, with muffled heart sounds. If dyspnea is noted, the hemothorax should be drained; however, if ventilation is adequate the chest should not be tapped, and the blood will gradually resorb. To evacuate the chest, a 14-gauge catheter or thoracic trocar is placed using aseptic technique in the ventral aspect of the 6th–8th intercostal space. Ultrasound helps guide placement, to prevent accidental penetration of vital structures. Aspiration can be facilitated by use of a 3-way stopcock and 60-mL syringe or provided by passive drainage with a Heimlich valve. Complications of trocarization can include pleuritis due to introduction of bacteria, continued hemorrhage, and hypovolemic shock if the fluid in the third space is removed too quickly. Conservative fluid therapy should be provided for cardiovascular support, and a transfusion may be needed.

Penetrating Abdominal Wounds: Penetration of the abdominal cavity is a serious and potentially fatal injury that can lead to hemorrhage, penetration of an abdominal

organ, or development of peritonitis. If a penetrating wound is suspected, it should be sterilely prepared, cleansed with saline and low-pressure lavage, explored for the presence of a foreign body, and debrided. A transabdominal ultrasound may reveal free fluid. Abdominocentesis can be performed to detect fecal contamination, indicating a ruptured viscus, or internal hemorrhage. However, abdominocentesis may not be diagnostic initially, because indicators of peritonitis (eg, increased total protein, WBCs, bacterial organisms) take several hours to develop. The wound should be bandaged, and broad-spectrum systemic antibiotics and pain management initiated. In the presence of a large wound, or if the abdominal musculature is involved, the abdomen can be supported with a compressive support bandage.

Head Injuries

Head injuries can result in severe CNS damage. Injuries can be primary (eg, contusion, laceration, fracture, hemorrhage) or secondary (eg, subsequent edema, reperfusion injury, secondary necrosis). Therapy of head injury is designed to minimize secondary CNS damage.

Causes of head injury in horses include direct trauma from a fall or blows to the head. A common cause of head injury is when the horse falls over backward onto the poll. Injuries associated with this fall include basisphenoid fractures and avulsion of the ventral straight muscles (longus capitus and/or rectus capitus ventralis muscles) from the base of the skull. Basisphenoid fractures can result in acute optic nerve damage and cerebral signs. Temporary or permanent blindness may result. Rupture of the ventral straight muscles may cause severe epistaxis, requiring transfusion, and avulsion fractures at the muscular insertion onto the skull may contribute to additional CNS injury.

The diagnosis is made by radiographs or CT to identify skull fractures, avulsion fractures, or a soft-tissue opacity in the guttural pouch (consistent with a hematoma from rupture of the ventral straight muscles). Endoscopy may show hemorrhage from the guttural pouch originating from the base of the stylohyoid bone or medial wall of the guttural pouch. Hematomas may be noted in the guttural pouch septum where the ventral straight muscles lie. Hemorrhage caused by fractures may also be seen draining from the ethmoid turbinates.

Treatment: Treatment of head injuries is mainly supportive to reduce secondary CNS damage. Horses with head injuries can be severely ataxic and should be handled and moved with extreme caution. If the horse is recumbent, short-term general anesthesia is best to transport the horse to a referral facility for further evaluation. Opioids should be avoided for sedation of horses with head trauma because of the risk of decreased cerebral perfusion pressure. The horse should be given IV fluids to maintain normal blood pressure and reduce the risk of cerebral ischemia. Diuretics are contraindicated. If hypoventilation develops, the horse should be intubated, and ventilation assistance provided to prevent hypercapnea. If the blood-brain barrier has been breached by a fracture, broad-spectrum antibiotics should be started. NSAIDs are administered to minimize inflammation, and seizures should be managed with diazepam (0.5–0.44 mg/kg, IV) or phenobarbital (5–15 mg/kg, given slowly IV). Although controversial for traumatic brain injury in human medicine, corticosteroids may be indicated in the acute phase of injury (eg, dexamethasone, 40–100 mg, IV). DMSO (1 g/kg, IV, in 5 L balanced electrolyte solution every 12 hr) has also been used to minimize secondary edema and decrease intracranial pressure. More effective for treatment and prevention of edema is 20% mannitol (1 mg/kg, IV, every 6–12 hr) or 7.5% hypertonic saline (4–6 mL/kg, IV, every 6–12 hr). Magnesium (0.05 mg/kg, IV, over 30 min) has also been proposed as a therapeutic agent to reduce cerebral ischemia.

Ocular Injuries

Ocular injuries are usually traumatic in origin and include periorcular lacerations, corneal lacerations, foreign body penetrating injuries, and direct blows to the eye, causing retinal detachment. (See also OPHTHALMIC EMERGENCIES, p 1696.) Evaluation of acute ocular injury includes a thorough evaluation of the structures of the eye (including the eyelids, conjunctiva, cornea, and lens), a fundic examination, and evaluation of cranial nerve function to assess the degree of damage. Vision can be assessed by the menace response and obstacle course testing. Oculomotor, trochlear, and abducens nerve function are assessed by the position of the eye and pupillary light responses. Facial nerve and sympathetic innervation to the eye are assessed by eyelid tone and position of the eyelashes.

Treatment of acute ocular injuries includes minimizing pain and inflammation,

preventing infection, and preventing further injuries. If penetration by a foreign body is suspected, rapid surgical intervention is indicated. Eyelid lacerations should be sutured, with assistance of a palpebral nerve block and local infiltration of an anesthetic. Sutures should be placed carefully to prevent corneal abrasion, and skin should be preserved during debridement. Anti-inflammatory medications administered to minimize pain and inflammation include NSAIDs and topical osmotic agents. Pain from pupillary spasm can be minimized by dilating the pupil with atropine and covering the eye to prevent myosis in bright sunlight. Acute injuries can be associated with corneal ulceration and secondary bacterial or fungal invasion. Use of broad-spectrum topical antibiotic and an antifungal medication may prevent secondary infection of a corneal ulcer. Horses that are acutely blind cannot move around their environment well. Further injury should be prevented by protecting the blind eye and by careful handling.

Thermal injuries

Thermal injury to a horse is rare. Most cases involve barn fires, lightning, electricity, caustic chemicals, or friction. Most burns are superficial, easily managed, inexpensive to treat, and heal in a short time.

Classification: Like those in people, burns in horses are classified according to the depth of injury. First-degree burns involve only the most superficial layers of the epidermis. These burns are painful and characterized by erythema, edema, and desquamation of the superficial layers of the skin. The germinal layer of the epidermis is spared, and the burns heal without complication.

Second-degree burns involve the epidermis and can be superficial or deep. Superficial second-degree burns involve the stratum corneum, stratum granulosum, and a few cells of the basal layer. Tactile and pain receptors remain intact. Because the basal layers remain relatively uninjured, superficial second-degree burns heal rapidly with minimal scarring, within 14–17 days. Deep second-degree burns involve all layers of the epidermis, including the basal layers. These burns are characterized by erythema and edema at the epidermal-dermal junction, necrosis of the epidermis, accumulation of WBCs at the base of the burn zone, eschar (slough produced by a thermal burn) formation, and minimal pain. The only germinal cells spared are those within the ducts of sweat glands and hair follicles.

Deep second-degree burn wounds may heal spontaneously in 3–4 wk if care is taken to prevent further dermal ischemia that may lead to full-thickness necrosis.

Third-degree burns are characterized by loss of the epidermal and dermal components, including the adnexa. These burns, when fresh, range in color from white to black. There is fluid loss and a marked cellular response at the margins and deeper tissue, eschar formation, lack of pain, shock, wound infection, and possible bacteremia and septicemia. Healing occurs by contraction and epithelialization from the wound margins, or acceptance of an autograft. These burns are frequently complicated by infection.

Fourth-degree burns involve all of the skin and underlying muscle, bone, ligaments, fat, and fascia.

Pathophysiology: After severe burns, there is a dramatic cardiovascular effect termed burn shock, which resembles hypovolemic shock. Local and systemic capillary permeability increases dramatically in response to heat and the release of cytokines, prostaglandins, nitric oxide, vasoactive leukotrienes, serotonin, histamine, and oxygen radicals. Because heat is slow to dissipate from burn wounds, it is often difficult to accurately evaluate the amount of tissue damage in the first 24–72 hr after injury. The extent of the burn depends on the size of the area exposed, while the severity relates to the maximum temperature the tissue attains and the duration of overheating. This explains why skin injury often extends beyond the boundaries of the original burn.

Management: Administration of isotonic fluids, at a rate of 4 mL/kg/% burn, in the first 24 hr (one-half of which is given in the first 8 hr) is recommended, but fluid resuscitation is best titrated to maintain stable and adequate blood pressure. An alternative is to use hypertonic saline solution (4 mL/kg) followed by administration of isotonic fluids. If there has been smoke or heat inhalation injury, crystalloid administration should be limited to the amount that normalizes circulatory volume and blood pressure. Continuing to administer electrolyte solutions at the same rate after burn shock has resolved leads to edema, which counters any improvement in cardiovascular dynamics. During fluid administration, hydration, lung sounds, and cardiovascular status should be monitored carefully by clinical assessment and PCV and total protein measurement.

Flunixin meglumine (0.25–1 mg/kg, IV, 1–2 times daily) is an effective analgesic. Firocoxib (0.1 mg/kg/day, PO) is a COX-2 inhibitor for horses. Although COX-2 inhibitors would seem beneficial in the management of burn patients, firocoxib is approved only to alleviate musculoskeletal pain. Human studies have found a synergistic effect of ketamine and morphine to ameliorate pain of skin burn injuries. Pentoxifylline (8 mg/kg, IV, bid) is used to improve the flow properties of blood by decreasing its viscosity. Administration of dimethylsulfoxide (DMSO) at 1 g/kg, IV, for the first 24 hr, may decrease inflammation and pulmonary edema. If pulmonary edema is present and is unresponsive to DMSO and furosemide treatment, dexamethasone can be administered once at 0.5 mg/kg, IV.

The cornerstones of therapy for smoke inhalation injury are maintenance of airway patency, adequate oxygenation and ventilation, and stabilization of hemodynamic status. Antibiotics and corticosteroids do not influence survival rates and should not be routinely administered. Systemic antimicrobials are indicated only for proven infections, the incidence of which increases 2–3 days after smoke inhalation. Procaine penicillin IM is effective against oral contaminants colonizing the airway. If signs of respiratory disease worsen, a transtracheal aspirate should be submitted for culture and sensitivity testing, and the antibiotic regimen adapted accordingly. Horses with suspected significant smoke inhalation should be observed closely for several hours and hospitalized if burns are extensive. Successful treatment depends on continual patient reassessment, as well as early and aggressive care.

First-degree burns are generally not life-threatening and thus simply managed. Second-degree burns are associated with vesicles and blisters. These vesicles should be left intact, because blister fluid provides protection from infection and an intact blister is less painful than the denuded exposed surface. An antibacterial dressing such as silver sulfadiazine is applied to the wounds while an eschar is allowed to form. Third-degree burns can be difficult to manage. The horse's systemic condition should be stabilized as rapidly as possible before undertaking wound management. Destruction of the dermis leaves a primary collagenous structure called an eschar. The eschar does not prevent bacterial contamination or evaporation of heat or water. The eschar should be covered with an antibacterial agent twice daily. Wound contraction does not occur while the eschar is intact.

The eschar is sloughed by bacterial collagenase activity within 4 wk. The exposed bed can then be grafted or allowed to contract.

Although bacterial colonization of large burns in horses is not preventable, the wound should be cleansed 2–3 times daily, and a topical antibiotic reapplied to reduce the bacterial load to the wound. Occlusive dressings should be avoided because of their ability to produce a closed wound environment, which may both encourage bacterial proliferation and delay healing. Amnion can decrease the pain of the wound and is antibacterial. It is more useful in areas of the body where it can be firmly pressed into the wound, such as the distal limbs. Additionally, circulation to the burned areas is often compromised, making it highly unlikely that parenteral administration of antibiotics can achieve therapeutic levels within the wound.

The most commonly used topical antibacterial for the treatment of burns is silver sulfadiazine in a 1% water miscible cream. It is a broad-spectrum, antibacterial agent able to penetrate the eschar. Silver sulfadiazine is active against gram-negative bacteria, especially *Pseudomonas*, with additional effectiveness against *Staphylococcus aureus*, *Escherichia coli*, *Proteus*, Enterobacteriaceae, and *Candida albicans*. It causes minimal pain on application but must be used twice a day because it is inactivated by tissue secretions.

Many burn patients suffer pruritus such that measures must be taken to prevent self-mutilation of the wound. Reserpine (2.5 mg, PO, for 7–10 days), normally used in horses as a long-acting tranquilizer, can effectively decrease the urge to scratch by successfully breaking the itch-scratch cycle. Weight loss of 10%–15% during the course of illness is indicative of inadequate nutritional intake. Gradually increasing concentrate, adding fat in the form of vegetable oil, and offering free-choice alfalfa hay increase caloric intake.

OTHER COMMON EQUINE EMERGENCIES

Esophageal Obstruction

(Choke)

Intraluminal esophageal obstruction is a common emergency in horses and is caused by impaction of ingested feed material. The most frequent sites of impaction are the proximal esophagus and just cranial to the thoracic inlet. Predisposing factors include

bolting of feed, poor dentition, recent sedation, poor feed quality, recent feed changes, and dehydration. *See also* ESOPHAGEAL OBSTRUCTION, p 215.

Diagnosis: Clinical signs of choke include nasal discharge containing saliva and feed material, hypersalivation, coughing, retching, signs of colic, or frequent attempts to swallow. The horse may be observed repeatedly stretching and extending the head and neck. Esophageal obstruction is identified by palpation of a foreign body in the neck, passage of a nasogastric tube, or esophageal endoscopy. In refractory cases, radiography and contrast radiography may be used, particularly if a foreign body, stricture, diverticulum, or esophageal rupture is suspected. Ultrasonography may identify thoracic changes consistent with aspiration of feed.

Treatment: Once the presence of an obstruction has been confirmed, the horse should be muzzled, and feed and water withheld. Acute, simple obstructions may resolve with sedation and consequent relaxation of the esophageal musculature. An α_2 -agonist such as xylazine or detomidine provides good muscle relaxation. Oxytocin (0.11 mg/kg, IV) has been demonstrated to provide good esophageal relaxation and has been used to resolve esophageal obstructions. Adverse effects may include mild signs of colic, and this drug should not be given to pregnant mares. The obstruction should resolve within 1 hr after administration of a muscle relaxant. If the horse is dehydrated, IV fluids may also help to resolve the obstruction.

If the obstruction has not resolved within ~1 hour after sedation, or if the choke is chronic (>3 hr duration), the horse should be sedated again to allow the head to drop for lavage of the esophagus. A nasogastric tube is passed, and gentle lavage with water is performed to flush the esophagus. Mineral oil should never be used because of the risk of aspiration pneumonia. An esophageal lavage tube (a nasogastric tube with a cuff) is useful to help resolve the obstruction and reduce feed aspiration. Alternatively, a cuffed endotracheal tube can be passed through the nasal passages and into the esophagus, and a smaller nasogastric tube used for lavage. These procedures can be repeated intermittently and can be aided by general anesthesia. If unsuccessful, an endoscope can be used to identify the obstruction and facilitate manual removal using endoscopic forceps.

After the obstruction has been relieved, endoscopy can be used to assess the esophageal mucosa. Circumferential ulceration can lead to stricture formation with recurrence of obstruction. Horses that have been choked are at risk of recurrence in the 2–4 wk after the initial event, even without visible esophageal damage. Feeding a slurried, pelleted diet or grass can prevent recurrence. When the esophagus has been damaged, narrowing is maximal 30 days after the obstruction. Before attempts are made to resolve a potential stricture, the horse should be managed medically with dietary modification for 60 days to allow for remodeling of the scar tissue. Broad-spectrum antibiotics are administered to prevent or treat aspiration pneumonia, along with anti-inflammatory drugs and tetanus prophylaxis. Sucralfate (20–40 mg/kg, PO, tid-qid) has been advocated to facilitate healing of esophageal ulceration.

Rectal Tears

Rectal tears are serious and possibly life-threatening injuries in horse. Prevention is key, but if a rectal tear occurs, appropriate and timely referral can result in a successful outcome. Rectal tears are classified into four grades based on the number of layers involved. Grade I tears involve the mucosa and submucosa only; grade II involve the muscularis only, with a mucosal-submucosal hernia; grade III involve the mucosa, submucosa, and muscularis, leaving the serosal layer intact; and grade IV involve all layers of the rectum, including the serosa. In the case of grade III tears, further classification is made based on the location of the tear; grade IIIa tears leave the visceral peritoneal intact, and grade IIIb tears are located dorsally in the mesentery. Most tears resulting from rectal palpation are located dorsally and extend into the mesocolon. Retroperitoneal tears are rare but have been reported. Fecal contamination often occurs with grade IV tears, but bacterial translocation and peritonitis is still possible with grade III tears. *See also* RECTAL TEARS, p 190.

Diagnosis: A rectal tear is suspected when there is sudden loss of resistance during palpation and when a copious amount of fresh blood is present on the rectal sleeve. Blood-tinged mucus usually indicates mucosal irritation only. If a tear is suspected, the severity should be immediately assessed and measures taken to initiate treatment or referral.

The horse should be sedated for assessment of the tear, and an epidural performed if there is any straining. N-butylscopolammonium bromide (0.3 mg/kg, IV) may be given to decrease peristalsis. A lidocaine enema may also reduce straining. A speculum should not be used, because it can worsen the tear. Digital palpation (preferably bare handed) is then carefully performed. A thin flap of tissue indicates a tear through only the mucosa. If a large cavity with a thin membrane is noted, a grade III tear is present. If intestine can be palpated, the tear is a grade IV. Visual confirmation can be made carefully using colonoscopy.

Treatment: Grade I and II tears can be medically managed with antibiotics, a laxative diet (mineral oil, mashes of complete pelleted feeds or alfalfa pellets, fresh grass) and analgesics (flunixin meglumine) to facilitate defecation. Select grade III tears can be managed similarly, if necessary because of financial restrictions, but also require daily manual evacuation for up to 3 wk. Peritonitis is a risk, repeat epidurals are required, and the time commitment is substantial. For the best outcome, grade III and IV tears should be referred to a surgical facility. However, it is essential to prevent fecal contamination of the abdomen during transportation; therefore, rectal packing is highly recommended. The horse is sedated and an epidural performed using a combination of xylazine and mepivacaine. A tampon composed of a 7.5-cm stockinette filled with moist, iodine-soaked cotton, coated with surgical lubricant is inserted until it is located at least 10 cm cranial to the tear. The stockinette should be inserted before filling it completely to avoid enlarging the tear. The anus is then temporarily occluded with a purse-string suture or towel clamp. The horse should be given systemic, broad-spectrum antibiotics, NSAIDs, and appropriate tetanus prophylaxis. Prevention of fecal contamination by grade III and IV tears during referral has a direct influence on the success of the outcome.

At the referral facility, the tear is reassessed to identify additional damage sustained during transportation. An abdominal centesis is performed to check for peritonitis. After assessment, several treatment options are available. For grade II tears with no fecal contamination that are at risk of forming a diverticulum, primary repair using a rectal approach can be attempted using one-handed sutures. The

horse should be monitored carefully for development of a perirectal abscess, which will require surgical drainage. For retroperitoneal tears with fecal contamination, the tear can be packed with iodine-soaked gauze and the cavity cleaned out daily. In mares, the cavity can be drained into the vagina, and the tear closed primarily. A laxative diet and analgesics are provided to decrease the pain of defecation. The most serious complication of retroperitoneal tears is development of an abscess that migrates forward into the abdominal cavity. This is prevented by ensuring appropriate drainage into the rectum or vagina.

For grade III or IV tears in a caudal location, primary repair using sutures through a rectal approach can be attempted. A successful repair of a grade IV tear using a linear stapling device has been reported. This approach requires that the abdomen has minimal to no contamination. Alternatively, these tears can be treated through a ventral midline approach, followed by an antimesenteric incision in the caudal small colon and repair through the lumen. A celiotomy has the advantage of a large-colon enterotomy and lavage, thus reducing the fecal load on the suture line.

Grade III and IV tears can also be treated by insertion of a rectal liner using a ventral midline celiotomy. Rectal liners are made of a plastic ring glued to a rectal sleeve. The liner is introduced rectally by a nonsterile assistant and sutured to the small colon using an external circumferential suture pattern that allows the ring to slough in ~10 days, resulting in a small-colon anastomosis. The liner diverts the normal fecal passage until the tear has healed. In other cases, a loop colostomy can be performed to maintain patency of the distal segment. The colostomy is performed as the first step; after the tear has healed, colonic continuity is reestablished using a second surgical procedure. In all fecal diversion procedures, an attempt is made to close or approximate the tear. Laparoscopic suturing of rectal tears has been described experimentally.

Postcastration Evisceration

Postcastration evisceration is always a risk after open castrations, but the risk is increased in draft horses, in Tennessee Walking horses and Standardbreds (because of their larger inguinal rings), or after castration of an adult stallion. Evisceration typically occurs within 4 hr of castration, but is a risk for up to 6 days after surgery.

Diagnosis: Evisceration of omentum or small intestine is first identified by a structure hanging out of the surgical incision. It is important to instruct the owner to keep the horse quiet and to support the eviscerated structure(s) with a towel to avoid further stretching or damage. Examination quickly reveals what structure is involved, so that treatment can be initiated.

Treatment: For omental evisceration, the horse is restrained, and rectal palpation performed to ensure that only the omentum is involved. Prolapse of the omentum can usually be managed by sedation and emasculating the omentum as far proximal as possible. For more severe cases, the horse is placed under short-term general anesthesia, and the omentum and scrotum cleaned and sterilely prepared. The omentum is emasculated as proximal as possible, and the scrotum packed with gauze and closed. Systemic antibiotics and NSAIDs are administered, and the packing removed in 2 days. Barring complications, antibiotics are discontinued on day 3.

If the small intestine is eviscerated, a short-term general anesthetic is given. The intestine is copiously lavaged and examined for damage. Avulsion of the mesenteric vessels or intestinal compromise require resection. The scrotum should be sutured closed over the eviscerated bowel, and the horse referred to a surgical facility. If the intestine appears healthy, it is replaced in the abdomen, which often requires dilation of the internal inguinal ring. Care should be taken to replace the intestine within the peritoneal cavity through the inguinal canal, and not through a separate, iatrogenic opening. If the herniation cannot be reduced confidently, the scrotum should be packed, sutured closed, and the case referred.

If the herniation can be reduced, the inguinal canal and scrotum are packed with sterile gauze, taking care to prevent introducing gauze into the abdomen, and the scrotum is sutured closed. A short segment of gauze is left exposed. Alternatively, the external inguinal ring and vaginal tunic can be sutured closed primarily instead of packing. Systemic, broad-spectrum antibiotics and NSAIDs are administered, and the horse monitored closely for development of colic or ileus, which may indicate intestinal devitalization. Should that occur, the horse must be referred for abdominal exploratory surgery. If the horse progresses well, the packing can be removed in 48 hr, and antibiotics discontinued 24 hr after removal. It is advised to

perform a rectal examination before removing the packing to ensure herniation has not recurred and the intestine has not adhered to the packing material.

NEONATAL INTENSIVE CARE AND EMERGENCIES

Initial Assessment

Early recognition of abnormalities is of utmost importance for successful management of critically ill foals. (*See also* MANAGEMENT OF THE NEONATE, p 2087.) Immediately after birth, the cardiovascular and respiratory systems of the foal must adapt to extra-uterine life. These critical events can be undermined by factors such as inadequate lung development, surfactant deficiency (primary or secondary), viral or bacterial infection, placental abnormalities, in utero hypoxia, and meconium aspiration.

Spontaneous breathing should begin within 1 min of birth, and many foals attempt to breathe as soon as the thorax clears the mare's pelvic canal. During the first hour of life, the respiratory rate can be >60 breaths/min but should decrease to 30–40 breaths/min within a few hours. Auscultation of the thorax shortly after birth reveals a cacophony of sounds as airways are gradually opened and fluid is cleared. End-expiratory crackles are consistently heard in the dependent lung during and after periods of lateral recumbency. It is not unusual for a newborn foal to appear slightly cyanotic during the adaptation period, but this should resolve within a few minutes of birth. Similarly, the heart rate of a healthy newborn foal has a regular rhythm and should be at least 60 bpm after the first minute. Occasionally, arrhythmias (atrial fibrillation, wandering pacemaker, atrial or ventricular premature contractions) may be ausculted but should resolve within 15 min after birth. A continuous holosystolic, or machinery, murmur heard for the first few days after birth over the left side of the heart is consistent with patent ductus arteriosus. Various other systolic murmurs, thought to be flow murmurs, may be heard during the first week of life. Murmurs that persist beyond the first week of age, those that are loud (>2/6), or murmurs that cause exercise intolerance or hypoxemia should be investigated more thoroughly.

Foals are normally nonresponsive to stimulation while in the birth canal. This lack of responsiveness has led to the presumption of fetal death during dystocia. Diagnostics, including palpation

of a pulse in the tongue, neck, or limb, or palpation and auscultation of the thorax for a heartbeat should be performed to confirm the foal has died. If the foal's nose is accessible during parturition, nasotracheal intubation will allow measurement of CO₂ tension in the expired gas. A long endotracheal tube (size 7–12 mm outer diameter) with an inflatable cuff should be used. The tube is passed blindly into the ventral meatus using a finger to guide the tube. Proper placement can be determined by palpation of the throat. The cuff is inflated, and manual ventilation is performed with either 100% oxygen or room air. CO₂ tension is measured continuously with a capnograph or a single-use end tidal CO₂ monitor. End-tidal CO₂ varies in foals during parturition, depending on cardiac output and ventilation frequency, but it should be consistently >20 mmHg and is usually closer to 30 mmHg. Once manual ventilation of a living foal is established, it must continue until the foal is delivered.

The righting reflex is present as the foal exits the birth canal, as is the withdrawal reflex. Cranial nerve responses are intact at birth, but the menace response may take as long as 2 wk to fully develop. Absence of a menace reflex should not be considered diagnostic of visual deficits in newborn foals. The suckle reflex should be strong by 10 min of birth. Within 1 hr of birth, healthy foals demonstrate auditory orientation with unilateral pinna control. The normal pupillary angle is ventromedial in the newborn; this angle gradually becomes dorsomedial throughout the first month of life. Foals may attempt to rise within 20 min of birth; most should stand on their own within 1 hr and nurse by 2 hr. Some foals defecate shortly after standing, but many will not attempt to defecate until after successfully suckling, about 3 hr after birth. First urination is more variable, with

fillies usually urinating before colts. It is not unusual for colts to “drop” their penis when urinating for the first few days of life because of the persistence of a normal tissue frenulum within the prepuce. The penis should not be forced from the prepuce; the frenulum will resolve without treatment.

The gait of the newborn foal is hypermetric, with a wide-based stance. Extreme hypermetria of the forelimbs, usually bilateral but occasional unilateral, has been seen in some foals associated with perinatal hypoxia and ischemia, but this gait abnormality usually resolves without specific therapy within a few days. Spinal reflexes tend to be exaggerated in the neonate. Foals also exhibit an exaggerated response to external stimuli (eg, noise, sudden movement, touch) for the first few weeks of life.

Dystocia and Resuscitation

Most newborn foals make the transition to extra-uterine life easily. However, for those with difficulties (eg, dystocia, premature placental separation), it is of utmost importance to recognize and institute appropriate resuscitation procedures. A modified Apgar scoring system has been developed as a guide to initiate resuscitation and estimate the level of fetal compromise (see TABLE 11). A brief physical examination should also be performed before starting resuscitation, because of humane issues concerning resuscitation of foals with serious birth deformities (such as severe limb contracture and hydrocephalus, among others).

The initial assessment begins during the presentation of the foal in the birth canal. Although the following applies primarily to the birth of a foal from a high-risk pregnancy, quiet and rapid evaluation can be performed during any attended birth.

TABLE 11 MODIFIED APGAR SCORE FOR EQUINE NEONATES

Clinical Evaluation (first 20 sec of life)	Score: 1	Score: 2	Score: 3
Heart rhythm and rate	Regular, >60 bpm	Irregular, <60 bpm	Absent
Respiration	Regular	Irregular	Absent
Response to external stimulation (nose, ear)	Sneeze, ear flick	Grimace, weak ear flick	Absent
Muscle tone	Active, sternal	Some ability to flex limbs	Limp, lateral

The goal in the normal birth of a healthy foal is to minimally disturb the bonding process between mare and foal. This also applies to a high-risk birth, although some disruption of normal bonding is inevitable.

The strength and rate of any palpable peripheral pulse should be evaluated as the foal presents. The apical pulse should be assessed as soon as the thorax clears the birth canal. Bradycardia (pulse <40 bpm) is expected during forceful uterine contractions, but the pulse rate should rapidly increase once the chest clears the birth canal. Persistent bradycardia is an indication for rapid intervention.

The fetus is normally hypoxemic compared with the newborn foal, and this hypoxia is largely responsible for the maintenance of fetal circulation by generation of pulmonary hypertension. During normal parturition, mild asphyxia occurs and results in fetal responses that lead to a successful transition to extra-uterine life. If more than mild asphyxia occurs, the fetus is stimulated to breathe in utero; this is known as primary asphyxia. If the initial breathing effort resulting from the primary asphyxia is not effective, a second gasping period occurs within several minutes known as secondary asphyxia. If asphyxia does not improve, the foal enters a stage called "secondary apnea," which is irreversible unless resuscitation is initiated. Therefore, the first priority of neonatal resuscitation is establishing an airway and breathing for the foal. Foals that are not spontaneously breathing are assumed to be in secondary apnea.

The airway should be cleared of the fetal membrane as soon as the nose is presented. If meconium staining is present, the airway should be suctioned before delivery of the foal is complete, and before the foal breathes spontaneously to prevent aspiration. Suction should be continued to the level of the trachea if aspiration of the nasopharynx is productive. Suctioning should be brief and gentle; overzealous suctioning worsens hypoxia, which causes secondary bradycardia or cardiac arrest through vagal reflexes. Suctioning should stop once the foal begins to breathe spontaneously.

If the foal does not breathe or move spontaneously to right itself within seconds of birth, tactile stimulation is necessary (eg, drying with a towel). If tactile stimulation does not result in spontaneous breathing, the foal should be intubated immediately and manually ventilated. Mouth-to-nose ventilation can be used if

nasotracheal tubes or a bag-valve-mask is not readily available. Hyperventilation with 100% oxygen is suggested to be the best choice to reverse fetal circulation; however, evidence from human medicine suggests there are no apparent disadvantages in using room air instead.

Almost 90% of foals requiring resuscitation respond to ventilation alone and require no additional therapy. Nasotracheal intubation can be started while the foal is in the birth canal if the foal is not delivered rapidly (eg, dystocia). This blind technique may require some practice but can be lifesaving. The nasotracheal tube also provides a convenient site for administration of intratracheal medications, such as epinephrine. Once breathing is spontaneous, humidified oxygen should be provided via nasal insufflation at 8–10 L/min.

Chest compressions should be started if the foal remains bradycardic despite ventilation or if a nonperfusing rhythm is palpated. The foal should be placed on a hard surface in right lateral recumbency with the topline against a wall or other support to keep the foal from sliding. The resuscitator's hands are placed over each other either directly over the heart (the cardiac method) or at the highest point of the chest (the thoracic method). The cardiac method is theorized to push blood forward by directly compressing the heart, whereas the thoracic method pulls blood forward by altering the intrathoracic pressure; both methods are valid in the foal. Compressions are provided at a rate of 80–120 per min, depressing the thorax 40% of its diameter, and allowing the chest to fully recoil. The first round of compressions should last 30–60 sec to allow for assessment of progress and addition of medications; after that, each round of compressions should last 2–3 min, followed by a 10-sec break to allow for assessment of heart rate, pulses, and rhythm. If the foal's heart does not start immediately after compressions cease, the resuscitator should switch out to prevent fatigue, and compressions are continued. Breaths should be provided by an assistant at a rate of 8–10 per min during cardiac compressions, or 2 breaths for every 30 compressions if the resuscitator is alone. If the foal is not resuscitated after 10–15 min of compressions, cerebral hypoxia is likely to have made further resuscitation efforts futile.

Because ~5% of foals are born with fractured ribs, assessment for the presence of rib fractures should be performed before starting chest compressions. Some of these

fractures can be identified by palpation. Fractures typically occur between ribs 3 and 8, are usually multiple and consecutive, and are located in a relatively straight line along the part of the rib with the greatest curvature just dorsal to the costochondral junction. Unfortunately, their location over the heart can make chest compressions a potentially fatal exercise. Foals with rib fractures should be placed in lateral recumbency with the fractured ribs down for compressions. After resuscitation, ultrasound can be used to identify rib fractures that have escaped detection by palpation, or new fractures caused by compressions. Ultrasound is the most sensitive diagnostic tool to identify rib fractures.

Drug therapy should be started if a nonperfusing rhythm persists for >30–60 sec in the face of chest compressions. Epinephrine remains the drug of choice at a dosage of 0.01–0.02 mg/kg, IV. If given through the nasotracheal tube, the dosage should be 0.05–0.1 mg/kg. Epinephrine can be repeated every 2–3 min during compressions, coinciding with the 10-sec assessments between rounds of compressions. Vasopressin (0.6 U/kg, every 10–20 min) is gaining attention as a cardiovascular resuscitation drug, but experience in foals is limited. Atropine is not recommended in bradycardic newborn foals, because the bradycardia is usually secondary to hypoxia. Atropine can also increase myocardial oxygen debt if hypoxia is not corrected. Doxapram is not recommended for resuscitation of newborns, because it does not reverse secondary apnea.

Immediately after birth, the foal must adapt to independent thermoregulation. In response to the catecholamine surge associated with birth, uncoupling of oxidative phosphorylation occurs within the mitochondria, releasing energy as heat. This nonshivering thermogenesis is impaired in newborns undergoing hypoxia or asphyxiation, and in those ill at birth. Human infants born to mothers sedated by benzodiazepines are similarly affected, a consideration in the choice of sedative and preanesthetic medications in mares with dystocia or undergoing cesarean section. In addition to nonshivering thermogenesis, thermoregulation in the healthy foal is supported by a high metabolic rate, a thick hair coat, fat stores, and the ability to shiver within minutes of birth. Heat losses by convection, radiation, and evaporation are quite high in most areas where foals are

delivered, resuscitated, and managed, and care must be taken to ensure that cold stress is minimized in newborn and critically ill foals. The foal should be dried and placed on dry bedding once resuscitation is complete. Supplemental heat in the form of radiant lamps or warm air circulating blankets may be required.

Fluid therapy should be used conservatively in postpartum resuscitation. The neonate is not volume depleted unless excessive hemorrhage has occurred. Some compromised newborns are actually hypovolemic. Because the renal function of the equine neonate is substantially different from that of adult horses, fluid therapy cannot simply be scaled down. If IV fluids are required for resuscitation and blood loss is identified, administration of 20 mL/kg of a polyionic, isotonic, glucose-free fluid over 20 min (~1 L for a 50-kg foal) can be effective. Indications for this shock bolus include poor mentation, poorly palpable peripheral pulses, and development of cold distal extremities compatible with hemorrhagic shock. The foal should be assessed after the initial bolus, and additional boluses (up to three) administered as needed. Glucose-containing fluids can be administered after resuscitation at a rate of 4–8 mg of glucose/kg/min (~120 mL/hr, 10% dextrose in balanced electrolyte solution to the average 50-kg foal), particularly in the obviously compromised foal. This therapy is indicated to maintain blood glucose levels, resolve metabolic acidosis, and support cardiac output, because myocardial oxygen stores have likely been depleted.

Prematurity, Dysmaturity, and Postmaturity

Traditionally, prematurity in horses is defined as a birth at <320 days gestation. However, normal gestation length ranges from 310 days to >370 days in some mares, which makes it difficult to define maturity based solely on gestational age. Premature foals are small, with a fine, silky hair coat, generalized muscle weakness, joint and tendon laxity, incomplete cuboidal bone ossification, a domed forehead, and floppy ears. Foals born post-term, but small, are termed dysmature. These foals may also exhibit the characteristic signs of prematurity. Dysmature foals may have been classified in the past as “small for gestational age” and are thought to have suffered from placental insufficiency. A postmature foal is a post-term foal that has a normal axial skeletal size but is thin to

emaciated. The hair coat is generally long, and the teeth may have erupted in utero. Postmature foals are usually healthy foals that have been retained too long in utero, perhaps due to an abnormal signaling of readiness for birth. Postmature foals become more abnormal the longer they are maintained in utero, and they may suffer from placental insufficiency. They are most commonly born to mares ingesting endophyte-infested fescue (*see* p 3017).

Prematurity, dysmaturity, and postmaturity may all be associated with high-risk pregnancy. Iatrogenic causes include early elective induction of labor (based on inaccurate breeding dates) or interpretation of late-term colic or uterine bleeding as ineffective labor. Most often, the cause is idiopathic. Even if undetermined, the cause may continue to affect the foal after birth. All body systems may be affected by prematurity, dysmaturity, and postmaturity, and thorough evaluation is necessary.

Respiratory failure is common in these foals and is related to immaturity of the respiratory tract, poor control of respiratory vessel tone, and weak respiratory muscles, combined with poorly compliant lungs and a greatly compliant chest wall. It is usually not due to a surfactant deficiency. Most foals require oxygen supplementation and positional support for optimal oxygenation and ventilation. Effort must be expended to maintain these "floppy foals" in sternal recumbency. Some may require mechanical ventilation.

These foals also require cardiovascular support but are frequently unresponsive to commonly used pressors and inotropes, including dopamine, dobutamine, epinephrine, and vasopressin. Careful use of these drugs and judicious IV fluid therapy are necessary. Renal function, reflected in low urine output, is often initially poor because of a delay in making the transition from fetal to neonatal glomerular filtration rates. The delay can be due to true failure of transition or secondary to a hypoxic or ischemic insult. Fluid therapy should be used cautiously in these cases; an initial fluid restriction may be required to avoid fluid overload.

Many premature, dysmature, or postmature foals have suffered a hypoxic insult and present with all of the disorders associated with perinatal asphyxia syndrome, inducing neonatal encephalopathy (*see* p 2094). Treatment is similar to that of term foals with these problems. These foals are also predisposed to secondary bacterial infections and must be

examined frequently for signs consistent with early sepsis or nosocomial infection.

The GI system of these foals is not usually functionally mature because of a primary lack of maturity or secondary to hypoxia. Dysmotility and varying degrees of necrotizing enterocolitis are common, as are hyperglycemia and hypoglycemia. Hyperglycemia is generally related to stress, increased levels of circulating catecholamines, and a rapid progression to gluconeogenesis, whereas hypoglycemia is associated with diminished glycogen stores, the inability to engage gluconeogenesis, sepsis, and hypoxic damage. Endocrine function may be immature, particularly regarding the hypothalamic-pituitary-adrenal axis, and contributes to metabolic derangements. If possible, enteral feeding should be delayed until metabolic and cardiorespiratory parameters are stable, and parenteral nutrition provided. When enteral feeding is initiated, small volumes should be provided first and slowly increased throughout several days.

Musculoskeletal problems are frequent, particularly in premature foals, and include significant flexor laxity, periarticular ligament laxity, and decreased muscle tone. Premature foals frequently exhibit flexor laxity combined with decreased cuboidal bone ossification that predisposes them to crush injury of the carpal and tarsal bones if weight bearing is not strictly controlled. Physical therapy, in the form of assisted standing and controlled exercise, is indicated in the management of these problems; however, care should be taken to ensure that the foal does not become fatigued and stand in abnormal positions. Splints and casts only increase laxity in the limbs, although light bandages over the fetlock may be necessary to prevent injury if flexor laxity is severe. Glue-on shoes may help improve the weight-bearing axis. If tube casts are used, they should not extend below the fetlock to minimize laxity, and they should be changed regularly to prevent sores. These foals are also predisposed to angular limb deformities and must be closely monitored for development of this problem as they mature. Postmature foals may be affected by flexural contracture deformities, most likely due to decreased intrauterine movement as they increase in size. (*See also* FLEXION DEFORMITIES IN HORSES, p 1150.)

The overall prognosis for premature, dysmature, and postmature foals remains good with intensive care and attention to detail. Many foals survive and become

productive athletes. Complications associated with sepsis and musculoskeletal abnormalities are the most significant indicators of poor athletic outcome.

Neonatal Encephalopathy

A wide spectrum of clinical signs is associated with neonatal encephalopathy, ranging from mild depression with loss of suckle reflex to grand mal seizures. Affected foals are typically healthy at birth but show signs of CNS abnormalities within a few hours. However, the timing of onset of clinical signs varies; some foals are obviously abnormal at birth, and some do not show clinical signs until 24 hr of age. Neonatal encephalopathy is commonly associated with adverse peripartum events, including dystocia, placentitis, twinning, and premature placental separation. However, some foals have no known evidence for the cause of the hypoxic event, suggesting that unrecognized in utero hypoxia occurred. (See also p 2094.)

Therapy for the various manifestations of hypoxia and ischemia involves control of seizures and cerebral edema; support of cerebral perfusion; correction of metabolic abnormalities; maintenance of normal blood gas values, tissue perfusion, and renal function; treatment of GI dysfunction; prevention, recognition, and early treatment of secondary infections; and general supportive care. Seizures must be controlled, because they increase cerebral oxygen consumption by 5-fold. Diazepam (0.1–0.44 mg/kg, IV) and midazolam (0.04–0.1 mg/kg, IV slow) can be used for emergency therapy, but the foal must be monitored for respiratory depression. For severe or persistent seizures, phenobarbital (2–3 mg/kg, IV, bid-tid) or a constant-rate infusion of midazolam (2–5 mg/hr for a 50-kg foal) may be instituted.

Sepsis

Sepsis in foals can be quite subtle initially, and the onset of clinical signs is variable depending on the pathogen involved and the immune status of the foal. Common pathogens include gram-negative bacteria, although gram-positive infections have been identified. Failure of passive transfer of immunity can contribute to development of sepsis in foals at risk. The current recommendation is that foals have an IgG level >800 mg/dL for passive transfer to be considered adequate. Other risk factors for development of sepsis include any adverse

event at the time of birth, maternal illness, or any abnormalities in the foal. Although the umbilicus is frequently implicated as a major portal of entry for infectious organisms, the GI tract may be the primary site of entry. Other portals of entry include the respiratory tract and wounds.

Early signs of sepsis include depression, decreased suckle reflex, increased recumbency, fever, hypothermia, weakness, dysphagia, failure to gain weight, increased respiratory rate, tachycardia, bradycardia, injected mucous membranes, decreased capillary refill time, shivering, lameness, aural petechiae, and coronitis. Survival rates of foals treated for sepsis have improved, but infection must be recognized early for the possibility of a good outcome. The pathogen involved can also affect survival. Gram-negative species are more commonly diagnosed, but gram-positive septicemia is being recognized more frequently, and multiple organisms may be involved. It is important to identify the organism early in the course of the disease. Blood cultures should be obtained, as well as samples from synovial fluid, CNS, peritoneal fluid, urine, and tracheal aspirates if localized signs are present. Until antimicrobial sensitivity patterns for the pathogen involved are obtained, broad-spectrum antimicrobial therapy should be started. IV amikacin (25–30 mg/kg/day, IV) and penicillin (22,000–44,000 U/kg, IV, qid) are good first-line choices, but renal function must be monitored closely. Other first-line antimicrobials include high-dose ceftiofur sodium (2–10 mg/kg, IV, tid-qid) or ticarcillin/clavulanic acid (50–100 mg/kg, IV, qid).

Failure of passive transfer should be treated, if present, with hyperimmune plasma. Intranasal oxygen insufflation at 5–10 L/min should be provided even if hypoxemia is not present, to decrease the work of breathing and provide support for the increased oxygen demands associated with sepsis. Mechanical ventilation may be necessary in cases of severe respiratory involvement seen with acute lung injury or acute respiratory distress syndrome. If the foal is hypotensive, pressor agents or inotropes may be administered by constant-rate infusion. Inotrope and pressure therapy is generally restricted to referral centers, where the infusions and the foal's blood pressure can be closely monitored. NSAIDs are used by some practitioners, as are corticosteroids in specific circumstances. Use of these drugs should be judicious, because they may

have several negative consequences, including, but not limited to, renal failure and gastric or duodenal ulceration. Antiulcer medications are controversial, because critically ill, recumbent foals typically have an alkaline gastric pH but may be useful once the foal is ambulatory.

Supportive care is important in treatment of septic foals. Foals should be kept warm and dry, and turned at 2-hr intervals if recumbent. Every attempt should be made to keep the foal sternal to improve respiratory function and reduce atelectasis. Feeding septic foals can be a challenge if GI function is abnormal; total parenteral nutrition may be needed. If at all possible, foals should be weighed daily and blood glucose levels monitored frequently. Some foals become persistently

hyperglycemic on low glucose infusion rates. These foals may benefit from constant-rate infusions of insulin. Recumbent foals must be examined frequently for decubital ulcers, corneal ulcers, and for heat and swelling associated with the joints and physes. Physical therapy or passive range of motion exercises should be provided.

The prognosis for foals in the early stages of sepsis is fair to good. Once the disease has progressed to septic shock, the prognosis becomes less favorable, although short-term survival rates are similar to those seen in human patients. Long-term survival and athletic outcomes are fair. Racing-breed foals that make it to the track perform similarly to their age-matched siblings.

VACCINATION OF EXOTIC MAMMALS 2054

AMPHIBIANS

The class Amphibia is composed of three orders: Anura (frogs and toads), the largest with >3,500 species; Caudata (salamanders, newts, and sirens) with ~375 species; and Gymnophiona (caecilians) with ~160 species.

ENVIRONMENT AND HUSBANDRY

Captive amphibians require proper environmental conditions to remain healthy. Natural stressors, including temperature

change, food availability, and habitat loss, combined with anthropogenic stressors, such as exposure to pesticides, fertilizers, heavy metals, nitrogenous wastes, and acidification, likely increase amphibian susceptibility to disease, contributing to the large population losses documented in recent years. As ectotherms, amphibians thermoregulate by shuttling back and forth between different temperatures in their environment. The range of temperatures necessary for proper metabolism, called the preferred optimal temperature zone

(POTZ), varies among species. Metabolism, including the regulation of immune function and digestion, can be adversely affected if animals are kept at temperatures outside of their POTZ. Infectious diseases and malnutrition are common problems in tropical amphibians kept at suboptimal temperatures.

Amphibians require moisture to prevent desiccation. Aquatic amphibians may be accommodated in aquariums with appropriate areas for swimming. Terrestrial amphibians need a shallow container of water in the enclosure. Moisture may also be provided by incorporating small streams, waterfalls, or ultrasonic humidifiers into enclosures, or by misting frequently with a spray bottle. Because amphibians have a semipermeable skin that readily absorbs potentially harmful substances, the water must be clean and free of toxins such as chlorine, ammonia, nitrite, pesticides, and heavy metals. Chlorine can be removed from tap water by placing the water in a barrel and circulating it through a carbon filter for ≥ 24 hr before use. Some municipal water supplies may include chloramines. The chloramine bond must be split with specific dechlorinating agents, after which water can be filtered to remove the chlorine. External canister filters or under-gravel filters help maintain water quality in tank waterfalls, streams, and ponds.

Substrates that can be used include gravel, soil, sphagnum moss, and mulch. Gravel should be either too large to be swallowed or small enough to be easily passed in the feces. Soils with chemical additives such as fungicides must not be used. Substrates such as sphagnum moss, untreated hardwood mulches, and leaf litter can be used, but cedar and pine mulches have toxic oils and should be avoided. Some amphibians cannot tolerate low pH and may develop skin irritation if they come into contact with peat moss and sphagnum moss. Heating soils to 200°F for 30 min is recommended to kill arthropods, such as trombiculid mites, and helminth parasites. Freezing substrates at $<32^\circ\text{F}$ also effectively removes many infectious organisms.

Adequate ventilation (1–2 fresh air changes/hr) is needed to prevent disease in amphibians. Live plants are recommended furnishings for terrestrial amphibians as they purify the air, remove organic wastes in the soil, filter light, generate humidity, and provide hiding and perching places. Aquatic plants oxygenate the water, remove nitrogenous waste, provide hiding places, and are often a source of nutrition for larval amphibians. Full-spectrum lighting using bulbs that

emit biologically active ultraviolet-B (280–320 nm) is recommended to prevent metabolic bone disease. Bulbs must be changed every 6–8 mo or according to the manufacturer's specification.

Longterm maintenance of most captive amphibians requires live food. Although most adult terrestrial and aquatic amphibians feed on invertebrates, including earthworms, bloodworms, black worms, white worms, tubifex worms, springtails, fruit flies, fly larvae, mealworms, and crickets, some amphibians feed on vertebrates and require live minnows, guppies, goldfish, or neonatal mice or rats. Vitamin and mineral supplements are necessary to prevent nutritional disease. These are commonly administered by "gut loading" insects, using commercially available diets high in calcium or by coating insects with powdered multiple-vitamin preparations that include vitamin D₃ and calcium (also known as "dusting").

Bleach (30 mL/L of water) can be used to disinfect tools and housing materials. A minimum of 30 min of contact time is recommended, after which the tools should be thoroughly rinsed with fresh water and preferably dried before use. Several sets of tools should be kept on hand when working with more than one colony of animals. Humidifiers and spray bottles must be disinfected weekly to remove potentially pathogenic bacteria, including *Pseudomonas* spp and *Aeromonas* spp.

CLINICAL TECHNIQUES

All possible routes of escape from the examination room, such as ventilation ducts and sink drains, should be blocked before handling amphibians. Recommended supplies include a mist bottle containing dechlorinated water, which can be used to keep amphibians moist when handled, dip nets, a small air pump with airline and air stone, a water quality test kit, a small room humidifier, tryptic soy broth blood culture vials, the anesthetic tricaine methane-sulfonate, and a microliter syringe. Fine-tipped culture swabs, glass slides, coverslips, scalpel blades of various sizes, an assortment of needles and syringes, sterile red-rubber tubes, and sterile saline should also be readily accessible.

The history should include a description of the animal's diet and appetite; environmental conditions of the animal's habitat, including humidity, temperature, water quality measures, and lighting regimen; social structure and reproductive status; the recent introduction or loss of animals; and

the use of medications. Problems noted by owners should be described in detail. A review of food and water quality records is useful to identify important trends. A water sample from the animal's enclosure should be analyzed for ammonia, nitrite, pH, hardness, alkalinity, and copper using a simple test kit readily available from most pet stores. Owners must take and record air and water temperatures at the time of water collection.

Before handling, the animal's body condition, agility, posture, and behavior should be noted. Parasitic or microbial infections, malformation, or nutritional deficiencies may cause asymmetry. Loss of muscle mass commonly occurs as a result of improper nutrition, improper environmental temperatures, or chronic disease (eg, mycobacteriosis, chromomycosis, microsporidiosis). Neurologic impairment may be detected by first watching the animal move about its enclosure and then assessing its response to the introduction of stimuli. Neurologic impairment may also be suspected if an amphibian is unable to maintain equilibrium or exhibits an abnormal swimming pattern. When handled, most normal amphibians attempt to escape, withdrawing limbs that are grasped. Placed upside down, most species will attempt to right themselves. Touching the eyes typically elicits a blink reflex or withdrawal of the globe.

A cool, bright light and magnification are required when performing a physical examination. The mouth can be opened using the edge of an index card, a plastic card, or a rubber spatula. The color of the mucous membranes should be evaluated and any lesions noted (eg, retrobulbar injury, orogastric intussusception). Ulcerations, erythema, hemorrhage, and pigment loss in the skin may indicate poor husbandry, trauma, or infections (microbial or parasitic). Improper substrate or sanitation leading to bacterial and fungal infections can cause lesions on the feet. Touch preparations or skin scrapings of affected areas are easily made and can be stained with Wright-Giemsa and Gram stains for cytologic evaluation. Heart rate can often be determined by watching the skin overlying the xiphoid or using a hand-held 8-MHz transcutaneous Doppler system. Because pulmonic respiration (if present) depends on positive pressure ventilation from buccal pumping, respiratory rate should be assessed by watching the rapid movements of the intermandibular space. The nares should be free of obstruction from mucus, which may

indicate respiratory disease. *Rhabdias* spp, a nematode that has a direct life cycle, is a common cause of respiratory infections in captive amphibians. Eggs or larvae may sometimes be detected in oropharyngeal mucus. Ocular lesions are often detected and may include conjunctival, corneal, iridal, and lenticular changes. Corneal diseases, including nonspecific keratitis and lipid keratosis, are common. Corneal scrapings are easily collected for cytologic examination. Panophthalmitis and uveitis are associated with systemic or localized infection. A sample of aqueous or vitreous humor can be collected with a small-gauge needle for cytology and for bacterial and fungal culture. Coelomic palpation may detect retained egg masses, bladder stones, foreign bodies, or neoplasms. Hydrocoelom and subcutaneous edema (anasarca and ascites) are common and may be caused by lymph heart failure; cardiac failure; renal, GI, or hepatic disease; neoplasia; microbial infection; parasitism; toxicosis; improper environmental conditions; or other unknown factors. Collection of fluid for biochemical analysis, cytologic evaluation, and culture for bacteria and fungi is recommended. Blood collected from the ventral abdominal vein, lingual vein, femoral vein, coccygeal vein, or by cardiac puncture and placed into lithium heparin can be used for hematologic evaluation. A volume equal to 1% of the body weight of a healthy amphibian and 0.5% of the body weight of a sick amphibian may be taken. Normal values have not been established for most species of amphibians. Urine may be collected for analysis from those anurans that urinate when first restrained. Fecal samples uncontaminated by environmental organisms may be collected from species such as dart frogs by feeding the animal just before placing it on a clean, moist paper towel. Direct and float examinations are useful to identify protozoa and metazoa.

Treatments are administered orally, topically, or by injection. Oral administration requires firm restraint and opening the mouth with a piece of waterproof paper or thin piece of plastic (such as a credit card). Guitar picks, which come in a variety of thicknesses, work well. Small amphibians can be dosed accurately using a microliter syringe. Many drugs may be administered topically; the skin of most amphibians will absorb drugs directly. Some drugs, such as enrofloxacin, may be irritating, and alternative routes may be preferable. Treatments may also be delivered topically by placing the amphibian in a medicated bath. Bubble wrap or other nonabrasive

material placed strategically over the amphibian may be needed to keep it in contact with the solution. Injections are typically given intracoelomically, into the lymph sacs, or intravenously.

Anesthesia: Anesthesia may be required for further examination or for diagnostic and surgical procedures. Response to anesthetics depends on individual health and species of the animal. Tricaine methanesulfonate, ketamine hydrochloride, propofol, halothane, isoflurane, and sevoflurane may be used. Routes of administration include immersion bath, topically, or parentally. Inhalant anesthetics are typically used topically or via an immersion bath, because they are readily absorbed through the skin. Larger amphibians can be intubated and maintained on anesthetic gas. Parental anesthetics are typically injected IV, IM, intracoelomically, or into the dorsal lymph sac. Injections into the rear limbs are avoided because of the presence of a renal-portal system. Heart rate can be monitored in most amphibians using an ultrasonic Doppler positioned over the heart. A baseline heart rate should be established before initiating anesthesia. Because amphibians can breathe through the skin, observing gular movement is less rewarding. Tricaine methanesulfonate is a fine white crystal that is highly soluble in water. It can be prepared and stored as a 10 g/L stock solution, which is diluted just before use. Administration is by bath, because most amphibians will absorb tricaine through the skin. The dosage used for many large amphibians is 2–3 g/L for induction. For short procedures, the amphibian should be immediately removed and rinsed with fresh water. For longer procedures, the amphibian may be placed into a maintenance solution of 100–200 mg/L after it has been induced. In smaller amphibians, an induction dosage of 100–200 mg/L is safer. Aeration must be provided in the anesthetic solution to avoid hypoxia. Tricaine produces an acidic solution that must be buffered to a pH of ~7 using sodium bicarbonate, sodium hydroxide, or sodium hydrogen phosphate. Isoflurane gas can also be bubbled into an anesthetic bath placed in a sealed container; this will allow both percutaneous and inhalation absorption. Ketamine hydrochloride injected percutaneously or into the dorsal lymph sac at a dosage of 75–125 mg/kg body wt can be used; however, a surgical plane of anesthesia can be difficult to maintain,

and recoveries are long. Intracoelomic injections of propofol at a dosage of 35–45 mg/kg body wt will also provide sedation to anesthesia.

INFECTIOUS DISEASES

Bacterial Diseases: “Red-leg” syndrome commonly refers to the hyperemia of the ventral skin that accompanies systemic infection in amphibians. Saprophytic, gram-negative bacteria such as *Aeromonas*, *Pseudomonas*, *Proteus*, and *Citrobacter* spp typically cause red-leg. Viruses, fungi, and other pathogens may cause similar lesions. Ventral hyperemia is a nonspecific sign and may also be seen with toxicosis. Malnourished, newly acquired amphibians that are maintained in poor-quality water or other inappropriate environmental conditions are particularly susceptible. Clinical signs include lethargy; emaciation; ulcerations of the skin, nose, and toes; and characteristic cutaneous pinpoint hemorrhages of the legs and abdomen. Hemorrhages may also be seen in the skeletal muscles, tongue, and nictitating membrane. In acute cases, these signs may be absent. Histologic evidence of systemic infection may include inflammatory or necrotic foci in the liver, spleen, and other coelomic organs. Blood or, if present, coelomic fluid, should be taken for culture before beginning therapy. Individuals can be treated initially with enrofloxacin

Red-leg syndrome in two leopard frogs. The larger frog is more severely affected. Courtesy of Research Animal Diagnostic Laboratory, University of Missouri.

(5–10 mg/kg/day, PO or IM), oxytetracycline (50 mg/kg, PO, bid), or chloramphenicol (50 mg/kg, PO, bid) before receiving culture and sensitivity results. If fungal infection is suspected, a 0.01% itraconazole bath (3.5 L fresh water mixed with 35 mL itraconazole solution; 5 min/day for 8 days) may be effective.

Mycobacteriosis, caused by acid-fast bacilli, including *Mycobacterium fortuitum*, *M. marinum*, *M. chelonae*, *M. abscessus*, *M. avium*, *M. szulgai*, and *M. xenopi*, is found principally in debilitated amphibians. Although often an infection of the integument, ingestion of infectious organisms may also lead to GI disease and systemic infection. Affected amphibians may exhibit gray nodules in the skin, liver, kidneys, spleen, lungs, and other coelomic organs. Infected amphibians may eat well but still lose weight. Acid-fast bacilli may be detected in feces and oropharyngeal mucus. A premortem diagnosis can be made by finding acid-fast bacilli in animals with external lesions. Culture of mycobacteria requires special media such as Lowenstein-Jensen agar (cultured at 23°, 30°, and 37°C) but is frequently unsuccessful. In cases in which staining is inconclusive, confirmation using PCR is recommended. Treatment is not recommended for this potentially zoonotic disease, and euthanasia should be considered.

Chlamydiosis is a serious infection of amphibians. Based on histologic lesions and the presence of inclusion bodies, these infections were originally attributed to *Chlamydia psittaci*. Using molecular methods such as PCR, it has since been shown that other species of *Chlamydia* have been associated with these infections, including *C. pneumoniae*, *C. abortus*, and *C. suis*. *Chlamydia* spp have also been found in apparently healthy frogs, which raises the question of whether these animals are a reservoir or vector for these infectious organisms. The disease was originally recognized in a mass mortality of African clawed frogs (*Xenopus laevis*) fed uncooked beef livers. Infected frogs may die peracutely or exhibit lethargy, dysequilibrium, cutaneous depigmentation, petechiae, and edema. Histologically, intracytoplasmic basophilic inclusion bodies can be identified in sinusoidal lining cells of the liver and spleen. Secondary bacterial infections are frequently present in affected amphibians and must be treated appropriately. Antibiotic treatment, including doxycycline (5–10 mg/kg/day, PO) or oxytetracycline (50 mg/kg/day, PO), may be effective against chlamydial infection.

Fungal Diseases: Many of the fungi that infect amphibians are difficult to distinguish grossly because they produce similar clinical effects, including lethargy and skin ulcerations. Some fungi can be identified via the examination of a wet mount prepared from a skin scraping, whereas others require culture, histology, and special stains. Treatment includes proper hygiene and the use of topical or systemic antifungal agents such as itraconazole. Other antifungal drugs such as fluconazole may also be effective.

Chytridiomycosis is the most serious fungal infection in amphibians and has been implicated in the decline of wild and captive frog, toad, and salamander populations around the world. The causative agent, *Batrachochytrium dendrobatidis* (Bd), is a nonhyphal zoospore fungus identified in specimens preserved as far back as 1938, yet it was not until the 1990s that the organism was associated with large losses of Australian frogs. Chytrids are typically found in moist environments, where they feed on decomposing organic matter or are parasitic to plants and invertebrates. Amphibians are the only known vertebrate host for chytrid fungi. Postmetamorphic anurans are affected far more than caudates or larval amphibians. Tadpoles are usually subclinical, because Bd infects only tissues that contain keratin. Anuran larvae have keratin only in their mouthparts, which may become depigmented and sometimes damaged. Most caudate larvae do not have keratinized mouthparts. As larvae undergo metamorphosis and their skin becomes keratinized, Bd can spread over the animal, infect the stratum corneum of the epidermis, and cause mortality. The "drink patch," specialized skin located in the ventral pelvic region that absorbs water, and the digits are especially affected. Diagnostic samples are best taken from these regions for this reason. Because pathogenicity of Bd appears to decline above 25°–27°C, it is speculated that some amphibian populations living at higher elevations have disappeared because of the cooler temperatures associated with the winter months and possibly climate change. Although the exact mechanism of infection is unknown, Bd causes skin hyperkeratosis and subsequent sloughing, osmoregulatory disruption, electrolyte disruption, and cardiac arrest. Infection intensity (>10,000 zoospores) appears to be associated with mortality. Some amphibians, including the bullfrog (*Rana catesbeiana*) and the African clawed frog (*Xenopus laevis*) are less susceptible to Bd and may serve as reservoirs for the disease. Mobile zoospores contribute to the loss of whole

populations of amphibians. Clinical signs include abnormal posture, anorexia, lethargy, dehydration, hyperemia, excessive shedding of skin, pupillary miosis, and muscle incoordination. These signs may be mild to absent in infected caudates, emphasizing the importance of performing diagnostic tests. Visualizing the spherical, single-celled organisms in skin scrapings stained with Wright-Giemsa or Gram stains using a light microscope is diagnostic, but the organisms are not always readily seen. Real-time PCR performed on swabs of the integument or pieces of skin is diagnostic and provides rapid assessment of presence and quantity of zoospores. This is useful in screening and management of amphibian populations at risk, such as those undergoing transport or quarantine. On histopathology, zoosporangia containing zoospores are associated with hyperkeratosis and underlying dermal infection. Treatment includes the topical administration of itraconazole (0.01% bath for 5 min/day for 10–11 days) and maintaining animals well within their normal thermal range. The use of terbinafine (0.01% bath buffered using bicarbonate to a pH of 7.2–7.4 for 5 min/day for 5 days) may also be effective. If appropriate for the species, raising environmental temperatures for captive populations to $>23^{\circ}\text{C}$ may help halt the infection while medicated baths are used to eliminate Bd. Systemic antifungal drugs appear to be ineffective in treating this infection of the epidermis. Bd is a World Organization for Animal Health (OIE) notifiable disease.

Saprolegniasis refers to disease caused by several genera of opportunistic fungi or "water molds" that infect the gills and/or skin of aquatic and larval amphibians. When in water, newly affected animals appear to have a whitish cotton-like growth on their skin. As the fungal mat ages, it may become greenish due to the presence of algae. Once removed from water, the fungal mat collapses and is difficult to see. Other signs include lethargy, respiratory distress, anorexia, and weight loss. Skin ulcerations may occur as the infection progresses. A diagnosis of saprolegniasis is made by finding hyphae and the thin-walled zoospores in a skin scrape. Treatment with a malachite green dip (67 ng/L for 15 sec, once daily for 2–3 days) or copper sulfate (500 mg/L for 2 min, once daily for 5 days, then once weekly until healed) may be effective. Treatment of eggs with methylene blue may be effective. Secondary bacterial and parasitic infections may be present in animals with dermal ulcers. Poor water quality conditions should be corrected.

Chromomycosis is caused by pigmented or black fungi from several genera (eg, *Cladosporium*, *Fonsecaea*, *Phialophora*, *Ochroconis*, *Rhinocladosporium*, and *Wangiella*). These fungi may be found in organic substrates such as topsoil and decaying plant matter. Disease is either cutaneous or disseminated systemic; both have been seen in captive and wild populations of amphibians. Signs may include anorexia, weight loss, granulomatous skin lesions or ulcers, coelomic distention, and neurologic disease. Diagnosis is usually made postmortem by finding disseminated granulomas with pigmented fungal cells and hyphae. Culture is frequently unsuccessful; histopathology may be necessary to confirm the diagnosis. Treatment using itraconazole (10 mg/kg/day, PO, for 30 days) may be given, but the prognosis is poor once the infection is disseminated.

Zygomycosis, caused by fungi of the class Zygomycetes (*Mucor* spp, *Basidiobolus* sp, and *Rhizopus* spp), affects both wild and captive populations of anurans. Clinical signs include lethargy and multifocal hyperemic nodules with fungal growth on the ventrum. Disease progresses rapidly and results in mortality within 2 wk. Zygomycetes are found in the environment, especially soils and decaying matter, and are a normal component of the amphibian's GI tract. Successful treatment has not been reported, but advanced antifungal agents may be tried.

Mesomycetozoans are fungus-like microorganisms at the animal-fungal boundary. Those reported in the literature to infect amphibians include *Amphibiothecum* (previously *Dermosporidium*), *Amphibiocystidium*, and *Ichthyophonus*; however, continued molecular characterization of these organisms is ongoing, resulting in nomenclature changes and taxonomic reorganization. *Amphibiothecum* and *Amphibiocystidium* are spore-forming organisms that typically produce a nonlethal infection in anurans. Clinical signs include multifocal nodules and pustules, usually on the ventrum, that resolve in 4–8 wk. Microscopically encysted spores contain large cytoplasmic vacuoles. *Ichthyophonus* is pathogenic to salamanders and frogs living in the eastern half of the USA. Pre- and post-metamorphic life stages are infected. Clinical signs include muscle swelling in the thigh, rump, and tail and may appear nodular, especially in tadpoles. Debilitation may lead to mortality, especially in adults. Diagnosis

is based on histopathology or finding characteristic spores through microscopic examination of material from the lesions. There is no treatment other than supportive care.

Parasitic Diseases: Many of the protozoa and metazoa found in and on amphibians are not associated with disease unless the host amphibian is stressed or immunocompromised. Recently caught or transported amphibians are particularly susceptible to parasitism, as are those kept in poor hygienic conditions and outside their POTZ. Parasites with indirect life cycles tend to die out when wild-caught amphibians are brought into captivity if the intermediate or final host is not present. Conversely, infections by parasites with a direct life cycle may be magnified in a closed environment. Excellent hygiene is essential for parasite control and includes the routine removal of sloughed skin, fecal material, uneaten food, and carcasses from animal enclosures.

External parasites may be found by close examination of amphibians using magnification and a bright, cool light. A skin scrape or biopsy may be required to identify parasites causing nodules or epidermal lesions. Internal parasites are often identified through examination of fresh fecal samples. Some small frogs are translucent enough to allow the visualization of nematodes using transillumination. In some cases, metazoan and protozoan parasites are found only at necropsy. Finding flagellates, ciliates, and opalinids in the feces is normal and does not require treatment in healthy amphibians. Although many larval nematodes found in the feces are nonpathogenic, treatment is recommended because pathogenic and nonpathogenic species cannot be readily distinguished.

Most protozoans found in the GI tract, including ciliates, opalinids, and flagellates, are commensals. The ciliate *Tetrahymena*, although normally nonpathogenic, has been associated with mortality of salamanders. Trichodinids may be found in the urinary bladder or on the skin of amphibians and require treatment. Hemoflagellates are occasionally found and generally nonpathogenic but can result in anemia. Greater-than-normal loads of GI flagellates and other protozoa may be found in debilitated amphibians and require treatment aimed at restoring balance and not eliminating the protozoa. External dinoflagellates (eg, *Piscinoodinium*) and flagellates (eg, *Ichthyobodo*) can cause significant mortality, especially in larval amphibians.

Fecal samples collected by placing the amphibian on clean, moist paper towels helps to prevent contamination from free-ranging protozoa. Cloacal wash, gill clips, and skin scrapes are also diagnostic. Treatment using metronidazole is often effective for external and GI organisms. Sporozoans such as coccidia (*Eimeria* and *Isospora*) and microsporidians (*Microsporidium*, *Pleistophora*, and *Alloglugea*) may be incidental findings or parasitic. Clinical signs are nonspecific and include poor body condition and wasting. Myxozoa occasionally cause disease in amphibians and result in specific host/disease agent lesions. Treatment efforts are focused on providing supportive care.

Metazoa parasites include myxozoa, helminths, and arthropods. Myxozoa infections in amphibians generally do not cause mortality. Helminths that are pathogenic to amphibians include trematodes (*Ribeiroia*, *Clinostomum*) and nematodes (*Rhabdias*, *Strongyloides*, *Pseudocapillarioides*). Arthropods, such as the common fish parasites *Argulus* and *Lernaea*, may infect amphibian aquatic life cycle stages, whereas ticks and mites affect postmetamorphic terrestrial animals. Larval dipterid flies may consume amphibian eggs and embryos and feed on the tissues of adults. Two of the most significant metazoan infections in captive amphibians are caused by *Rhabdias* sp and *Pseudocapillarioides xenopi*.

Rhabdiasis, caused by the lungworm *Rhabdias* sp, commonly causes pulmonary damage and secondary infections in captive amphibians. This nematode has a direct life cycle with free-living phases. Adult worms live in the lungs, where they deposit larvated eggs that are coughed up, swallowed, and then excreted into the environment. Infective L₃ larvae then burrow through the skin of a new host, where they mature and migrate to the lungs. Affected animals may appear anorectic, thin, and generally debilitated. A premortem diagnosis may be made by finding ova or worms in oral and nasal secretions. Infection should be suspected when nematode larva and larvated eggs are found in fresh feces from an animal with clinical signs. When rhabdiasis is suspected, treatment using fenbendazole (100 mg/kg/day, PO, for 2 days then repeated 12–14 days later) or ivermectin (200–400 mcg/kg, PO, once, repeated 12–14 days later) is recommended. After the second of each 2-day fenbendazole treatment or each dose of ivermectin, the animals should be moved into a newly established environment to

prevent reinfection from free-living life stages. Some reactions to fenbendazole have been reported, so animals should be monitored closely and treatment discontinued if necessary.

The capillariid nematode *Pseudocapillaria xenopi* burrows into the skin and is known to affect colonies of the aquatic African clawed frog. Signs include discoloration, roughening, pitting, and ulceration of the skin. As the infection progresses, lethargy, anorexia, and skin sloughing occur. Diagnosis is made by finding small, white nematodes beneath the mucus on the skin; skin scrapings may show larvae and ova. Treatment by adding thiabendazole (0.1 g/L) to the water may be effective. Levamisole and other anthelmintics may also be effective. Frequent water changes with removal of shed skin containing the parasite are required to prevent the amplification and spread of infection to cage mates.

Viral Diseases: Renal adenocarcinomas (Lucké tumors), caused by ranid herpesvirus-1, are relatively common in leopard frogs (*Rana pipiens*) wild-caught in the northeastern and north central USA. Few frogs with tumors are seen in the summer, because viral replication is temperature-dependent. Virus particles and intranuclear inclusion bodies are seen when frogs are in hibernation, at 41°–50°F (5°–10°C). Metastasis of the tumor to liver, lungs, and other organs is common; both the primary and metastatic tumors can become very large. There is no treatment. The neoplasm is a model of herpesvirus-induced cancer.

Ranaviruses, which are DNA-based viruses in the genus *Ranavirus*, family Iridoviridae, have been identified as the cause of mass mortality in wild populations of anurans and caudates across the world. Environmental conditions, reservoir species, persistence in the environment, direct and indirect transmission, stress, and host immunity contribute to the impact of ranaviruses on amphibian populations. Species of *Ranavirus* that infect amphibians include frog virus 3 (FV3) and FV3-like viruses, *Bohle iridovirus*, and *Ambystoma tigrinum* virus. These viruses are highly virulent and may produce 90%–100% mortality in tadpoles and adults. Transmission occurs through exposure to contaminated water or soil, contact with infected individuals, and consumption of infected tissues. Fish and reptiles (especially turtles) are reservoirs for ranaviruses. Clinical signs are nonspecific, develop rapidly in a large number of cohorts, and include abnormal

swimming behavior, swelling of the limbs or body, edema, hydrocoelom, erythema, ventral skin hemorrhage (especially in the hind region), and occasionally skin ulcerations. Lesions may appear very similar to those of bacterial dermatosepticemias. The original viral lesions may be overwhelmed by secondary invaders, and many outbreaks of “red-leg” may have had underlying and undiagnosed viral infection. Death typically results from multiple organ failure. Amphibian larvae undergoing metamorphosis or recently metamorphosed juveniles seem to be most susceptible to infection. For this reason, mortality events often occur in the spring/summer. Survivors appear to acquire some immunity to future infections. Diagnosis is made using PCR, primary cell culture, and/or microscopy. Ranaviruses can persist in the aquatic environment without a host for weeks, which contributes to their ability to infect naïve amphibian populations and emphasizes the need for biosecurity measures when transporting amphibians or working in environments where the virus exists. Disinfection using bleach (1%) and chlorhexidine (0.75%) are effective. Ranavirus disease is notifiable to the World Organization for Animal Health (OIE).

NONINFECTIOUS DISORDERS

Nutritional Diseases: Metabolic bone disease is frequently seen in amphibians consuming nonsupplemented invertebrates. Except for earthworms, most invertebrates used as food have an inverse calcium:phosphorus ratio. This results in mandibular deformity, long bone fracture, scoliosis, and eventually tetany and bloating. Diagnosis is made radiographically by finding thinning cortices of long bones, mandibular and hyoid bone deformities, pathologic fractures, and in severe cases, GI gas. Treatment includes correcting the diet and administering calcium glubionate 1 mL/kg/day, PO, for 30 days. Full-spectrum lighting with biologically active ultraviolet-B light should be provided. Vitamin D₃ can also be administered in severe cases. Starvation, resulting in weight loss, lethargy, and dehydration, must be treated by providing proper nutrition through assist feeding.

Thiamine deficiency is seen in amphibians fed frozen fish containing thiaminase. Clinical signs include tremors, seizures, and opisthotonos. Initial treatment is the administration of thiamine at 25–100 mg/kg, IM or intracoelomic, followed by thiamine 25 mg/kg body wt, PO, with each meal. Thiamine deficiency can be prevented by

As metabolic bone disease in amphibians advances, pathologic fractures of the long bones are readily seen on radiographs.

Courtesy of the National Aquarium.

routinely supplementing diets with 250 mg thiamine/kg of fish feed.

The carotenoids, including vitamin A, are not synthesized by amphibians and must be provided through diet. Excessive levels of vitamin A have been hypothesized to interfere with vitamin D metabolism and contribute to metabolic bone disease, whereas deficiency has been associated with lethargy, wasting, and inability to use the tongue to catch prey due to the development of squamous metaplasia of the tongue (short tongue syndrome). Treatment includes providing vitamin A supplementation and force feeding a proper diet.

Obesity is a disease. Overfeeding is the primary cause of obesity; many amphibian species will continue to consume prey as long as it is available and without regard for their energy needs. The oversized fat bodies may be palpated within the coelomic cavity; however, in females, ultrasound may be necessary to differentiate enlarged fat bodies from egg masses. Treatment for active species includes enlarging the size of the enclosure to allow increased activity. Maintaining the amphibian at the upper end of its POTZ will accelerate metabolic rate and increase caloric use. Reducing caloric intake also may be used to control weight.

Neoplasia: Spontaneous neoplasia occurs in most organ systems but is rare except when caused by pollutants or an infectious agent, such as the virally induced Lucké renal carcinoma that affects populations of northern leopard frogs (*see above*) or epidermal papillomata in the Japanese firebelly newt. With increasing longevity in captivity and better health care, it is likely that more cases of neoplasia will be identified.

Trauma: Traumatic injuries are common in captive amphibians and include lacerations, bone fractures, internal bleeding, desiccation, and the loss of digits, limbs, or tail. Rapid assessment followed by supportive care is required for a successful outcome. Desiccation is common in amphibians that escape their enclosure or do not receive proper care. For smaller amphibians (<30 g), most fractures can be managed conservatively with cage rest. For larger amphibians, the use of external or internal fixation may be beneficial. Pain management must be considered in traumatic cases. The presence of opioid receptors suggests using opioids may be beneficial (buprenorphine, 0.02 mg/kg, IM, SC, or PO). NSAIDs may also be used (meloxicam, 0.2 mg/kg) and appear to provide pain relief.

EMERGENCY CARE

Initial emergency support includes providing fluid therapy, oxygen, and an environment of proper temperature and humidity. Placing the animal in a shallow bowl of isotonic or slightly hypotonic fluid enables transdermal uptake. Equal parts 2.5% dextrose in 0.45% sodium chloride and lactated Ringer's solution is effective. Coelomic, IV, or interosseous fluids may be given by bolus to larger animals at 5–10 mL/kg. In the absence of known exposure to an organophosphate, seizing animals should be treated for hypocalcemia (calcium gluconate, 100 mg/kg, IM, IV, SC, or intracoelomic, once or twice daily), organophosphate toxicity (atropine, 0.1 mg/kg, SC or IM as needed), and thiamine deficiency (vitamin B₁, 25–100 mg/kg, IM or intracoelomic as needed). If sepsis is suspected, antibiotic administration (eg, enrofloxacin 5–10 mg/kg/day, PO, SC, IM, or intracoelomic) should be initiated. Treatment for traumatic injuries is directed at minimizing blood loss, providing fluid therapy and respiratory support (doxapram 5 mg/kg, IM or IV as needed), and reducing pain (buprenorphine 0.02 mg/kg, IM, SC, or PO, or meloxicam 0.2 mg/kg), followed by corrective therapy.

AMPHIBIANS AS LABORATORY ANIMALS

Amphibians have long been used as laboratory animals. In an effort to enable scientific research while maintaining humane and ethical principles, the 8th edition of *The Care and Use of Laboratory Animals* (National Research Council, National Academies Press, 2011) provides organizations conducting research on animals, including aquatic animals, with information regarding environment, housing, management, and veterinary care. This guide should be consulted when using amphibians in research. (See also LABORATORY ANIMALS, p 1836.) Species that are captive born and readily available from commercial suppliers include the African clawed frog (*Xenopus laevis*, *X. tropicalis*), the African dwarf frog (*Hymenochirus boettgeri*), the fire-bellied toad (*Bombina orientalis*), the axolotl (*Ambystoma mexicanum*), and the tiger salamander (*A. tigrinum*). Wild-caught species collected by researchers or vendors for use in the laboratory include the northern leopard frog (*Rana pipiens*, sometimes called the grass frog), bullfrog (*R. catesbeiana*), cane toad (*Bufo marinus*, sometimes called the marine toad), and the mud puppy (*Necturus maculosus*). Other North American ranid frogs are sometimes used. When collecting or importing amphibians, it is important to abide by state laws and obtain all required permits.

Pelleted diets are available for some aquatic species, like African clawed frogs, bullfrogs, and axolotls, making it easier to feed large groups. These foods must be stored in a cool, dry location to maintain freshness. Uneaten food should be removed

after all animals appear satiated to avoid fouling the tank. Handling and research protocols should be developed to minimize stress to the animals. Overcrowding must be avoided to maintain sanitation, prevent disease transfer, and reduce social stress.

Most aquatic species used for laboratory studies are kept in large, recirculating systems that have multiple tanks using a common water supply. Water is filtered, sent to individual tanks, and then returned for filtration and disinfection. Proper water quality is maintained using one or more types of filtration. These include a mechanical filter to remove suspended waste material, a biofilter to convert nitrogenous wastes to less toxic compounds, and a chemical filter to remove dissolved organic compounds. The addition of an ultraviolet sterilizer to inactivate microorganisms is highly recommended. Bulbs must be kept clean and changed every 6–8 mo for the ultraviolet sterilizer to remain effective. Ozone, a potent oxidant, may also be used with caution to remove suspended organic material and potential pathogens from the water.

Ammonia toxicosis is common in systems that have not established a good biofilter. Amphibians exposed to inappropriate levels of ammonia typically produce excess mucus, become dull in color, and attempt to escape. Amphibians should be removed from the contaminated water and rinsed thoroughly with dechlorinated and well oxygenated fresh water. A diagnosis can be confirmed if the source water has ammonia at levels >0.5 ppm, although toxicity can be seen at levels >0.1 ppm for some species. Many tropical fish stores sell test kits that check for ammonia.

AQUACULTURE

Aquaculture is the production of marine and freshwater organisms under controlled conditions. Hundreds of different species of aquatic animals are raised in aquaculture and include fish and aquatic invertebrates cultured for food, the aquarium hobby, bait, recreational fisheries, research, private ponds, and stock enhancement of wild populations. Animal aquaculture was valued at \$137.7 billion (USD) worldwide in 2012, with China's production valued at \$66 billion

and the USA's at \$1 billion. Within the USA, major commercial commodities include channel catfish, centered around the Mississippi Delta; rainbow trout in the north/northwest, including Hagerman Valley, Idaho; Atlantic salmon in the Pacific northwest and Atlantic northeast; aquarium fish with production centered in Florida; baitfish in Arkansas; and goldfish and koi production scattered throughout the USA. In addition, other public and private entities,

including research facilities, public aquaria, and hobbyists, are breeding numerous other species.

PRODUCTION METHODS

Aquaculture production methods vary greatly, but regardless of method, a good understanding of water quality and chemistry, species requirements, and systems design and operation will facilitate good management. Production can be divided into two major categories: land-based and open-water systems. Land-based facilities use tanks and ponds to house and raise fish. Tank systems can be flow-through, in which continuous replenishment of "new" water comes from a well, reservoir, or other central water body; recirculating, with reuse of system water after filtration to remove nitrogenous wastes and dissolved and suspended particulates; or a combination of the two. Indoor, land-based tank systems afford much greater control over water quality, predators, and pests than outdoor facilities, but often house fish at much higher densities.

Design and management of recirculating aquaculture systems (RASs) requires greater technical knowledge than for flow-through systems (see Southern Regional Aquaculture Center [SRAC] Fact Sheet 4708 [<https://srac.tamu.edu>]). Most RASs typically incorporate biologic filtration and mechanical filtration components, although some also include some type of chemical filtration and in-line sterilization. Biologic filters rely on the establishment of two sets of nitrifying bacteria on biofiltration surfaces to transform ammonia, a by-product of protein and nucleic acid metabolism by fish from food, first into nitrite (a toxic intermediate), and then into nitrate, considered a much less toxic compound (although levels of nitrate may be problematic for invertebrates and, at higher levels, fish). More advanced systems include a denitrification component that transforms nitrate into nitrogen gas that is released into the atmosphere. Mechanical filters remove particulates to reduce their negative effects on water quality and fish health, and to improve water clarity, which facilitates observations. Chemical filtration is used to change the concentration of specific ions or compounds in the water (eg, ion-exchange resins such as those used in softeners to remove calcium, or zeolite to bind ammonia). Ultraviolet (UV) sterilization units and ozone are common choices for

aquaculturists who wish to include in-line disinfection of system water. UV sterilizers act optimally at a wavelength of 254 nm and disrupt pathogen DNA. Systems with these components typically include a system bypass loop to feed a portion of total system water into these disinfection units. UV sterilizing units must be designed and rated to deliver a specific "zap dose" to target a specific pathogen or pathogen group. Component maintenance, water clarity, wattage, and water flow through the UV sterilizer all contribute to the efficiency of the unit. Although there are exceptions, in general the larger and more complex a pathogen is, the greater the zap dose required to kill it. Ozone units use highly reactive O_3 to break apart microorganisms. However, because ozone can be very harmful to fish, it must be removed from the water before it is returned to the system. Ozone is also a human health hazard, so protocols to safeguard human health should be implemented. *See also* AQUATIC SYSTEMS, p 1766.

Pond systems include earthen and lined ponds typically filled from wells, aquifers, or surface water bodies. Ponds have minimal water exchange and rely on good management of their more "natural" systems to maintain acceptable water quality and control aquatic weeds, algae, and other pond life. Nitrifying bacteria are found on surfaces in the pond. Important key water quality parameters—oxygen, carbon dioxide, and pH—can vary widely throughout the day in a pond because of photosynthesis by phytoplankton (algae) and other plant life. During the day, photosynthesis increases oxygen levels. However, during the evening, when photosynthesis has ceased, oxygen is consumed by all organisms in the pond, including algae and higher plants, resulting in lower levels. At the same time, increased production of carbon dioxide (without consumption through photosynthesis) results in lowering of pH. During the day, these trends are reversed. Any ammonia levels in a pond will have increased toxicity as pH rises throughout the day. Other challenges in pond production include pests and predators, such as snails, otters, birds, amphibians, and reptiles, as well as nontarget fish, all of which can also act as reservoirs or vectors for pathogens or intermediate hosts. *See also* AQUATIC SYSTEMS, p 1766.

Channel catfish, tilapia, hybrid striped bass, shrimp, crawfish, baitfish, and ornamental fish are raised in ponds, tanks, or a combination of the two. Some species, including rainbow trout, require higher oxygen concentrations and are raised in land-based raceways.

Open-water aquaculture includes production in net pens or sea cages placed in oceans, bays, lakes, or reservoirs. Open-water systems rely on good flushing, dilution, and natural processes occurring within the given water body to maintain acceptable culture parameters. In many cases, land-based systems are used for reproduction and early life-stage growout for “open water aquaculture” species. Open-water systems do have a number of challenges. Water quality in the main body of water cannot be controlled. Access (by boat in many cases) and logistics are more complex because of location within a larger body of water. Biofouling (growth of algae, bacteria, other invertebrates) on nets can reduce water exchange and degrade water quality within the net or cage. Pests and predators can be more difficult to control, as can human theft or vandalism. Disease management is also more complex because of increased environmental restrictions in natural water bodies and treatment logistics (eg, modifications such as “tarping” (placing a large polyethylene liner over or under a net to hold water for temporary bath/immersion treatments).

Open-water systems are used for final grow-out stages of clams, oysters, mussels, Atlantic salmon, flounder, pompano, cobia, and other marine species. Production of some freshwater species (eg, tilapia) may also use net pens set in lakes, ponds, or reservoirs for growout.

PRODUCTION MEDICINE AND BIOSECURITY

General veterinary approaches in aquaculture parallel those for other production animals, such as large animals and poultry. When working with fish, disease prevention is always more rewarding than treatment. Once fish are sick, accurately identifying all present problems can be difficult, and treatment must be administered early in the course of an epizootic to be effective.

A comprehensive program of fish health management should be based on the principles of good husbandry and biosecurity. Good husbandry practices, including water quality, systems management, and nutrition, facilitate health and prevent disease. Consequences of poor husbandry are magnified in production aquaculture because of the greater size and density of populations in a production setting than in a hobbyist or aquarium display system. Population health is the focus (although valuable broodstock may warrant individual care), with preventive medicine of critical importance.

Populations can vary from several individuals to millions, with many facilities averaging thousands to hundreds of thousands within any given defined population.

Biosecurity underlies critical fish health management practices for disease prevention and management (see SRAC Fact Sheets 4707, 4708, and 4712 [<https://srac.tamu.edu/index.cfm/viewAllSheets/>]). Good biosecurity will minimize the risk of introduction and spread of an infectious disease into and within a facility, as well as minimize the risk that diseased animals or infectious agents will leave the facility and spread to other sites. Major biosecurity goals include good animal management, obtaining and maintaining healthy stocks through good sourcing and husbandry, pathogen management, and people management through education and awareness for staff and visitors. See also BIOSECURITY, p 2068.

Animal Management: Eggs and animals should be from a reputable supplier, and animals should be screened for species-specific health parameters and diseases of concern. Previous testing and other relevant historical and husbandry information should be obtained for any lots of fish entering a facility. New fish should undergo quarantine to prevent spread of disease. Water quality, other environmental conditions (such as choice of holding units, density, water flow, lighting, and sound), and nutrition should be optimized for the facility's goals and species.

Pathogen Management: Water source is a major risk factor for disease introduction, with protected water sources (ie, sources that do not have fish or other potential pathogen reservoirs) having low to zero risk of carrying diseases of concern. Examples of protected water sources include those from deep wells or disinfected municipal supplies. Protected water sources are preferable to unprotected sources, such as surface waters from a lake or river. Risks from unprotected sources can be mitigated (eg, through filtration, UV sterilization, chlorination, and/or ozonation) to make them safer.

Efforts to maintain as clean an environment as possible, including minimal accumulation of organic debris, proper disinfection of nets and equipment, and thorough disinfection of fish-holding units between groups of fish, help minimize disease outbreaks by optimizing water quality and reducing pathogen loads and reservoirs (see below). Familiarity with common diseases for a given species, as well as potential disease reservoirs and relevant diagnostics and control are important. Some pathogens,

such as the bacteria *Aeromonas hydrophila* and the ciliated protist *Trichodina*, are considered ubiquitous and opportunistic, whereas others may result in significant morbidity and mortality (eg, *Streptococcus* spp or *Amyloodinium*), and/or have regulatory consequences (eg, infectious salmon anemia or spring viremia of carp, a foreign animal disease in the USA). Quarantine of new fish at temperatures permissive for significant diseases will facilitate determination of presence of specific pathogens. Isolation of diseased populations, use of equipment dedicated to a specific group, and system and equipment sanitation and disinfection are important methods of pathogen management.

People Management: Important components of a good biosecurity program include owner and staff education, awareness, and commitment to principles of biosecurity. Written protocols and rules for workers and facility visitors help solidify understanding and accountability. Increasingly, facilities are making the effort to develop written biosecurity, health management, and disaster management plans. Interested veterinarians should be familiar with aquaculture systems and be able to evaluate these protocols, as well as staff and visitor adherence to them through general biosecurity audits.

Cleaning and Disinfection: Proper cleaning and disinfection are critical components of a good fish health management program. There are a number of good references for cleaning and disinfection in aquaculture settings (see SRAC Fact Sheet 4707: Biosecurity in Aquaculture, Part 1, Tables 1 and 2 [<https://srac.tamu.edu>], and Guide to Using Drugs, Biologics, and Other Chemicals in Aquaculture, Table 5 [www.fws.gov/fisheries]).

Cleaning and disinfection of tanks and equipment starts with general cleaning and removal of dirt and organic debris. Organic debris, including biofilms, and dirt can shield pathogens from disinfection. Liquid household bleach (3%–6% NaHClO) delivered at 35 mL/gal. of water creates a concentration of 200 mg/L. Granular bleach (HTH, calcium hypochlorite) is more stable than household bleach and is often used on commercial farms. It is available in three different concentrations: 15%, 50%, or 65% available chlorine. The target dose of chlorine for disinfection is 200 mg/L for at least 1 hr. This concentration can be achieved by mixing 1.4 g of the 15% product/L of water, 0.4 g/L of the 50% product, or 0.32 g/L of the 65% product. These

products are strong oxidizers, and precautions listed on the label or relevant Material Safety Data Sheet should be followed when handling them. A 1-hr contact time at 200 mg/L will destroy most organisms of concern, including most viruses. Bleach should not be used in closed areas containing live fish, because the volatile compound may get into the solution and kill fish in nearby tanks. Mycobacteria are refractory to bleach disinfection because of their waxy cell wall. Spraying equipment and contact surfaces with alcohol after treatment with bleach should effectively eliminate mycobacteria, although access to some surfaces (eg, PVC pipework) and associated biofilms may be difficult. In these instances, it is understood that major reduction in pathogen numbers is the key goal. Another commonly used aquaculture disinfectant, Virkon® Aquatic (active ingredient 21.4% potassium peroxymonosulfate and 1.5% sodium chloride), is highly effective at 1%–2% concentrations and considered much less toxic to fish (manufacturer directions must be followed). Quaternary ammonium compounds such as Roccal® and benzalkonium chloride are also excellent disinfectants and can be used at concentrations of 500 mg/L for 1 hr, but residual films should be rinsed off completely. Both Virkon Aquatic and quaternary ammonium compounds are more suitable for net clips and net disinfection.

NECROPSY AND DIAGNOSTIC TECHNIQUES

For information on fish physiology, see *AQUARIUM FISHES*, p 1779. General methods for clinical evaluation of aquacultured species are similar to those used in aquarium fish. However, for more structured surveillance and pathogen testing, more uniform and standard methods may be required. OIE-accepted diagnostic methods for reportable diseases are described in *The Manual of Diagnostic Tests for Aquatic Animals* (also known as the *OIE Aquatic Manual* [www.oie.int]). Another good reference with standards for necropsy and diagnostics is *The American Fisheries Society Fish Health Section Blue Book* (2014 Ed.) *Suggested Procedures for the Detection and Identification of Certain Finfish and Shellfish Pathogens* (www.afs-fhs.org). Depending on the specific goals for testing (disease diagnostics, health certification, surveillance) and on the ultimate recipient of any testing results (eg, another state agency vs another country), one or both provide excellent information on methodology. Most veterinary practitioners will require

additional laboratory support for more advanced diagnostics (eg, virology, histopathology, bacteriology). Therefore, it is important that the laboratory is qualified and, for USDA-APHIS relevant documentation, approved by the USDA-APHIS to run specific diagnostic tests for aquaculture species.

THE NATIONAL AQUATIC ANIMAL HEALTH PLAN

The U.S. National Aquatic Animal Health Plan (NAAHP) (www.aphis.usda.gov) was developed to facilitate the legal movement of all aquatic animals, their eggs, and products in interstate and international commerce; protect the health and thereby improve the quality and productivity of farmed and wild aquatic animals; ensure the availability of diagnostic, inspection, and certification services; and minimize the impact of diseases when they occur in farmed or wild aquatic animals. The NAAHP is a federal guidance document intended to help direct federal, state, and tribal efforts in the areas listed above. Work is ongoing to continue to refine and implement relevant and urgent aspects of the NAAHP.

USDA-APHIS is the lead federal agency for commercial aquaculture and the protection of aquatic animal health. See the focus on fish health Web site (www.aphis.usda.gov/focusonfish/) for useful links to access additional information on the USDA-APHIS aquaculture program.

The OIE sets the standards for members of the World Trade Organization with regard to determination of internationally reportable diseases and their management, and monitors these diseases with the cooperation of member nations (*see* the Aquatic Animal Health Code [www.oie.int]).

REPORTABLE DISEASES AND REGULATORY CONCERNS

With increased regulation of ornamental and aquacultured fish in the USA, there are additional needs for professional veterinary services, including USDA health certification (*see* below) for movement of animals. Implementation of the NAAHP should more clearly define the role of veterinary practitioners in the future. USDA-APHIS provides voluntary training to practitioners who wish to work in this area and is developing a special aquatic certificate for accredited veterinarians. Information on federal regulations pertaining to fish medicine is available at www.aphis.usda.gov. State law may be more restrictive than federal law, and there is significant variation

in state regulations regarding importation of aquatic animals. The State Veterinarian or State Animal Health Officer is the ultimate resource for information on state animal health regulations.

Currently, USDA-APHIS has adopted the reportable disease list of the OIE (www.oie.int) as reportable in the USA (*see* TABLE 6, p 1786). If a USDA-APHIS reportable disease is suspected, appropriate samples should be collected as per the OIE Aquatic Manual. Practitioners should stay informed of changes in the status of diseases of regulatory concern, because they are liable if they have a case that is not reported. Regulated fish diseases of greatest concern to aquatic animal veterinarians in the USA include koi herpesvirus, spring viremia of carp, and viral hemorrhagic septicemia. Notification of reportable aquatic diseases should be made directly to the State Veterinarian and to the USDA Area Veterinarian in Charge.

Health Certification: A major role of the aquaculture veterinarian is health certification of many animals leaving a facility. Movement of animals may be intrastate, interstate, or international. Specific testing and general health requirements for aquaculture exports vary according to region, state, country, and species. In some instances, only a visual inspection is required, whereas in others statistically determined sample sizes and more standardized diagnostic methods are necessary. Level of required oversight also varies. Some countries require only evaluation and signature by a licensed veterinarian, whereas others require the oversight and acknowledgment of the national competent authority. USDA-APHIS is the competent authority for commercial aquaculture in the USA and provides information on specific import/export requirements by country (www.aphis.usda.gov). For importing countries requiring USDA-APHIS oversight, veterinarians must be licensed to practice in the USA and obtain veterinary accreditation (Category 2 accreditation is required for aquaculture) through USDA-APHIS for evaluation of aquaculture species. USDA-APHIS is also tasked to protect aquaculture in the USA from foreign disease introduction. For facilities within the USA that import fish, USDA-APHIS determines health requirements for incoming shipments, with fish, crustacean, molluscan, and amphibian diseases of concern listed by the OIE currently considered reportable by USDA-APHIS; however, not all of these are program diseases with specific actions required for positive cases.

THERAPEUTIC CONSIDERATIONS

Although improvement of water quality, nutrition, and other general husbandry factors may be enough to improve the health of a population, chemotherapeutics are often required to ameliorate disease outbreaks. Management of fish diseases is challenging because of basic logistics, including the aquatic environment, numbers of fish, and routes of administration, and also because of the pharmacologic and regulatory complexities of chemotherapeutic usage in fish.

One major point of confusion among veterinarians, more critical because of impacts on the aquatic environment, is the difference between a drug and a pesticide. Drugs are regulated by the FDA, whereas pesticides are regulated by the Environmental Protection Agency (EPA). According to the Federal Food Drug and Cosmetic Act definition, the term "drug" can be defined four ways: 1) articles recognized in the official United States Pharmacopoeia, official Homoeopathic Pharmacopoeia of the United States, or official National Formulary, or any supplement to any of them; or 2) articles intended for use in the diagnosis, cure, mitigation, treatment, or prevention of disease in man or other animals; 3) articles (other than food) intended to affect the structure or any function of the body of man or other animals; and 4) articles intended for use as a component of any of the aforementioned articles.

The EPA regulates water and effluents and controls the use of pesticides against "pests." A "pest" is defined by the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) as "any insect, rodent, nematode, fungus, weed" or "any other form of terrestrial or aquatic plant or animal life or virus, bacteria, or other microorganism (except viruses, bacteria, or other microorganisms on or in living man or other living animals)."

Legally, a drug is a compound that works in or on the fish, whereas a pesticide works in the water. Challenges occur for one of two reasons: 1) certain pathogens, and in particular some parasites, including the fish louse *Argulus* spp and anchorworm *Lernaea* spp, have life stages off the host and in the environment; and 2) certain compounds, such as copper and diquat, are legal pesticides but are also drugs effective against some pathogens.

FDA-approved Drugs, Indexed Drugs, Pesticides, and Regulatory Concerns

FDA-approved therapeutic options for fish are limited but increasing. The FDA Web site (www.fda.gov) is the best resource for basic

information on the status of drugs and chemicals, particularly those intended for aquaculture use. In addition, the FDA has listed several compounds as being of "low regulatory concern." These compounds, although not fully approved, are considered innocuous enough for use in food fish. Of these, salt is the most important. A few compounds, including copper sulfate and potassium permanganate, are not FDA approved but are legally available for limited use in food fish as part of a supplementary FDA data collecting process as Investigational New Animal Drugs. For more information, see <https://srac.tamu.edu/index.cfm/event/viewAllSheets/>, specifically the link for SRAC Fact Sheet 4709 (Investigational New Animal Drug [INAD] Exemptions and the National INAD Program [NIP]). Another category is drugs on the *Index of Legally Marketed Unapproved New Animal Drugs for Minor Species (the Index)*. Fish are considered by the FDA to be a minor species. The process of placing drugs on the *Index* involves the use of an expert panel and is intended to increase legal access to unapproved drugs intended for non-food-producing minor species (including non-food fish) and non-food early life stages of food-producing minor species (www.fda.gov). Currently, the only two fish drugs on the *Index* are AquacalmTM (metomidate), a fish sedative/anesthetic, and Ovaprim[®] (GnRH + domperidone), a spawning aid also used to "spawn out" egg-bound females under some conditions. See TABLE 1 for a summary of the approval status and withdrawal times of drugs used in aquaculture in the USA. Practitioners are encouraged to visit the FDA Web site frequently for the most current information.

Finally, a number of compounds that are not FDA approved are used in pet fish practice under controlled conditions. These drugs have no legal status and have no place in food animal practice. A term formerly used by the FDA, "regulatory discretion," has fallen out of favor, but it does provide some explanation of the FDA's current approach to use of unapproved, non-Indexed drugs. The primary concerns are degree and magnitude of impact on human and environmental safety, and regulatory action against any illegal use will be weighed against those two measures (see www.fda.gov for additional guidance).

In addition to being aware of FDA concerns, fish practitioners should be familiar with environmental regulations for drugs and pesticides. Federal and state environmental regulations are of greatest importance when treating outdoor ponds.

Considerations include potential for entry of treated water into natural water bodies or the water table and potential effects to nontarget species. Compounds labeled pesticides are regulated in the USA by the EPA and therefore cannot be used under extra-label drug use provisions regulated by the FDA (ie, these compounds cannot be used in a manner beyond their specific label, which would have to include an aquatic use section).

Three FDA-approved antibiotics are currently available for use in aquacultured food fish in the USA. Some of these products can be useful in ornamental fish, especially koi; however, extra-label use of FDA-approved medicated feeds is not permitted under current law. Recognizing the need to deliver some medications in a medicated food for fish, the FDA has indicated that it would not normally consider regulatory action against a veterinarian using medicated fish food in an extra-label manner if the following criteria are met: 1) the extra-label use is for treatment of a minor species as defined by federal law; 2) in an aquatic species, the use of medicated feed in an extra-label manner is limited to products approved for use in other aquatic species; and 3) a valid veterinarian-client-patient relationship is clearly established.

Veterinarians should also be familiar with the Veterinary Feed Directive (VFD). This is of particular interest to practitioners in rural areas, who may be asked to write prescriptions for aquacultured fish. For a veterinarian to issue a VFD order, there must be a valid veterinarian-client-patient relationship, and the veterinarian must have examined the fish and identified a bacterial disease that would be treatable with the VFD drug (eg, florfenicol). Extra-label use of the VFD drug, including use for species or pathogens not indicated on the label, is prohibited by law. However, VFD drugs may be legally accessible through enrollment in the appropriate INAD (see above).

A small group of compounds have been designated by the FDA as "high regulatory priority," meaning their use is likely to result in enforcement action. These drugs either have human or environmental safety concerns or are related to compounds considered critical for human health and disease. The most important of these compounds are chloramphenicol, the nitrofurans, fluoroquinolones and quinolones, steroid hormones, and malachite green. These compounds should never be used in food animals for any reason, and their use in nonfood species is discouraged.

Antibiotics

Aquaflor® is an approved medicated feed containing florfenicol for use against specific pathogens in enteric septicemia (*Edwardsiella ictaluri*) in channel catfish, coldwater disease (*Flavobacterium psychrophilum*) in salmonids, furunculosis (*Aeromonas salmonicida*) in freshwater-reared salmonids, streptococcal septicemia in freshwater-reared warmwater finfish, and columnaris disease (*Flavobacterium columnare*) in freshwater-reared finfish. It is marketed as a VFD product. This broad-spectrum antibiotic has excellent efficacy against many gram-negative bacteria and gram-positive streptococci, although as a VFD drug extra-label use is forbidden. However, as discussed, for INAD data collection purposes, use may be permitted in other species and for other indications in certain situations. The withdrawal time is 15 days.

Oxytetracycline dihydrate (Terramycin® 200 for Fish) is an in-feed medication approved 1) to control mortality in freshwater-reared salmonids due to coldwater disease associated with *F. psychrophilum*, 2) to control mortality in freshwater-reared rainbow trout due to columnaris disease associated with *F. columnare*, and 3) to mark skeletal tissue in Pacific salmon. All approved uses require a 21-day withdrawal period for harvest-size food fish species.

Ormetoprim sulfadimethoxine (Romet-30®) is an in-feed treatment approved by the FDA to control furunculosis (*A. salmonicida*) in salmonids, for which a 42-day withdrawal period is required, and to control enteric septicemia of catfish (*E. ictaluri*) in channel catfish for which a 3-day withdrawal period is required. Romet-30 can be used extra-label as long as there is a veterinarian-client-patient relationship and veterinary oversight.

Hydrogen peroxide 35% (Perox-aid®) is administered by immersion and is FDA approved for use in finfish to control bacterial gill disease (caused by *F. branchiophilum*) in salmonids, external columnaris (caused by *F. columnare*) in freshwater-reared coolwater finfish and catfish, and fungal infection (saprolegniasis) of freshwater-reared finfish eggs. These are common external infections in fish that may follow handling or be associated with high organic load or other water quality perturbations for the affected species. Hydrogen peroxide is used as a short-term, continuous-flow bath. Treatments are administered daily or on consecutive alternate days for three

TABLE 1

DRUGS USED IN AQUACULTURE IN THE USA – APPROVAL STATUS AND WITHDRAWAL TIMES

Active Ingredient	Trade Name	Generic Use
Florfenicol	Aquaflor®	Antibiotic
Oxytetracycline dihydrate	Terramycin-200®	Antibiotic
Ormetoprim sulfadimethoxine	Romet-30®	Antibiotic
Hydrogen peroxide (35%)	PEROX-AID®	Antimicrobial (gills and skin only)
Chloramine-T	HALAMID Aqua®	Antimicrobial (gills and skin only)
Diquat	Reward®	Herbicide Antibiotic (gills and skin only)
Formalin	Formalin-F TM Formalin-B Parasite-S®	Parasiticide (gills and skin only)
Copper sulfate (CuSO ₄)		Parasiticide (gills and skin only)
Potassium permanganate (KMnO ₄)		Parasiticide (gills and skin only)
Diflubenzuron	Dimilin®	Parasiticide (external crustaceans)
Tricaine methanesulfonate	Tricaine-S®	Anesthetic
Eugenol	Aqui-S20E®	Anesthetic
Metomidate	Aquacalm®	Sedative
Chorionic gonadotropin	Chorulon®	Spawning aid
sGnRHa + domperidone	Ovaprim®	Spawning aid

treatments. An initial bioassay is recommended before treating a large group of fish. Paddlefish are sensitive, and use of hydrogen peroxide is not recommended. Other sensitive species include northern pike, pallid sturgeon, and in some instances, walleye. Hydrogen peroxide can be used extra-label, and experimental use has been attempted in other species and for other indications, including as a parasiticide (see UF/IFAS EDIS publication *Use of Hydrogen Peroxide in Finfish Aquaculture* [<http://edis.ifas.ufl.edu/fa157>]). There is no required withdrawal time after treatment with Perox-aid®.

Other Chemotherapeutic Drugs

Formalin: Formalin is FDA approved for use in finfish and penaeid (saltwater) shrimp. Several brands have received FDA approval for aquaculture use. Methanol may be added to formalin products as a preservative. "Pure" 100% formalin is, technically, water saturated with ~37%–40% formaldehyde gas. Formalin eliminates protistan parasites and monogeneans from the external surface of fish. It also has some efficacy against external fungal infections. It can be used as a prolonged bath at concentrations of 15–25 mg/L. The lower concentration is recommended for pond

TABLE 1

DRUGS USED IN AQUACULTURE IN THE USA – APPROVAL STATUS AND WITHDRAWAL TIMES (continued)

Application Method	Approval Status ^a	Withdrawal Time
Medicated feed	FDA approved ^a (Veterinary Feed Directive)	15 days
Medicated feed	FDA approved	21 days
Medicated feed	FDA approved	42 days in salmonids; 3 days in catfish
Immersion	FDA approved	None
Immersion	FDA approved	None
Immersion	EPA	5 days in channel catfish, muskellunge, tiger muskellunge, northern pike;
Immersion	INAD required	30 days in all others
Immersion	FDA approved	None
Immersion	INAD required	7 days
Immersion	INAD required	7 days
Immersion	EPA ^a (restricted use pesticide)	Not for use in food fish
Immersion	FDA approved	21 days
Immersion	INAD required	72 hours
Immersion	The <i>Index</i>	Not for use in food fish
Injection	FDA approved ^a (prescription only)	None (broodstock)
Injection	The <i>Index</i>	Not for use in food fish

^aApproval status is of January 8, 2015. Practitioners should check the FDA Web site (www.fda.gov) frequently for the most current information.

use, because formalin removes dissolved oxygen from the water. Vigorous aeration during formalin treatment is essential. When treating at ≤ 25 mg/L, a water change is not necessary after chemical administration. At this concentration, formalin has minimal impact on biofiltration; however, if ammonia is tested using Nessler's reagent, a very high reading may be seen for several days. This is an artifact caused by the interaction of the two compounds. Use of the salicylate method to test ammonia is suggested when formalin has been used in a system. Short-term baths with formalin can be provided at concentrations up to 250 mg/L for 30 min, but a bioassay and close observation during

treatment is essential because 250 mg/L may be lethal in some fish. At water temperatures $>77^{\circ}\text{F}$ (25°C), the concentration should not exceed ~ 170 mg/L. If adverse reaction to the chemical becomes apparent, the fish should be immediately placed in clean water. If formalin is allowed to chill to $<45^{\circ}\text{F}$, a white precipitate, paraformaldehyde, will form. Because paraformaldehyde is highly toxic to fish, formalin should never be used if a precipitate or cloudiness is seen. Formalin is carcinogenic and potentially toxic to workers; material safety data sheets should be on hand in businesses where the chemical is used, and employees should be informed of appropriate safety precautions.

There is no required withdrawal time after treatment with formalin.

Chloramine-T: Chloramine-T (HALAMID Aqua®), a biocide and mild disinfectant, has been approved by the FDA for three indications: 1) to control mortality in freshwater-reared salmonids caused by bacterial gill disease associated with *Flavobacterium* spp, 2) to control mortality in walleye due to external columnaris disease (*F. columnare*), and 3) to control mortality in freshwater-reared warmwater finfish due to external columnaris disease (*F. columnare*). No withdrawal period is required before harvest.

Hypersalinity and Hyposalinity:

Hypersalinity (for freshwater systems) and hyposalinity (for marine systems) are often used in aquaculture and can be effective methods for control of some parasites. Hypersalinity in freshwater typically involves use of sodium chloride, which is considered “low regulatory priority.” In some instances, dilution of seawater may be used. Sodium chloride effectively mitigates nitrite toxicity (see AQUATIC SYSTEMS, p 1766) to reduce osmoregulatory stress in freshwater fish and to control some protistan and copepod parasite infestations. In some instances, seawater may be used. Salt is not generally practical for use in production ponds because of their large volume, except for control or prevention of nitrite toxicity, but it can be used in ornamental ponds that are not more than several thousand gallons. Salt is commonly used in recirculating aquaculture systems.

Copper Sulfate: Copper sulfate (CuSO_4) is currently an INAD not yet approved by the FDA; however, a number of compounds containing CuSO_4 have been approved by the EPA as algicides for use in aquatic sites. Technically, the chemical form of the commonly used blue crystal copper sulfate is $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$ (copper sulfate pentahydrate), but for purposes of brevity, the formula CuSO_4 will be used here, and this blue compound referred to as “copper sulfate.”

Copper sulfate is currently designated as “of moderate regulatory concern” and is used in food fish practice. CuSO_4 has been used for many years as a parasiticide and is particularly useful in large production ponds because of its relatively low cost. Copper is highly toxic to fish, and safe use depends on knowing both the volume of water to be treated and the total alkalinity, as well as potential species sensitivities.

In freshwater systems, the concentration of CuSO_4 is considered 100% active, and application should be based on the total alkalinity (TA) of the water. If TA is <50 mg/L, copper sulfate cannot be used safely. If TA is 50–250 mg/L, a safe concentration of CuSO_4 can be determined by dividing the TA by 100. For example, if TA = 100 mg/L, a safe concentration of CuSO_4 would be 1 mg/L. If TA is >250 mg/L, the concentration of CuSO_4 should not exceed 2.5 mg/L. CuSO_4 also has algicidal activity. Rapid death of an algal bloom can precipitate catastrophic oxygen depletion. Use of CuSO_4 in ponds not equipped with supplemental aeration is risky. Use of CuSO_4 is hazardous if a pond has a heavy algal bloom (secchi disk ≤ 18 in.) or if the water is already deficient in oxygen because of other factors (eg, cloudy weather, heavy stocking density, or high water temperature).

Copper in marine systems, by contrast, is dosed according to level of free copper ion (Cu^{2+}). Therapeutic concentrations are based on maintaining a longterm dosage range of 0.15–0.2 mg/L of free Cu^{2+} . As discussed earlier, “blue” copper sulfate is actually $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$, so for purposes of marine systems, copper sulfate is considered 25% active ingredient (the molecular weight of free copper is ~25% of the entire compound). Because copper is toxic and because treatment periods for susceptible marine pathogens often last for ≥ 2 –4 wk, copper should be added to a system slowly at 0.05 ppm/day to reach the target range of 0.15–0.2 mg/L over the course of 3–4 days. This allows the fish’s body to acclimate and activate detoxifying pathways to reduce toxic effects. Free copper levels should be monitored daily. Copper is highly toxic to many invertebrates, and even with slow acclimation some saltwater species are still fairly sensitive. The following formula can be used to calculate the grams of copper sulfate required to treat a marine tank: volume (in gal.) $\times$ 0.0038 $\times$ desired concentration $\times 4 = \text{g of CuSO}_4$.

Chelated copper compounds (copper sulfate or copper ion chelated with another chemical) have also been used in some circumstances, but caution should be used for legal reasons and when dosing for treatment. Copper can be removed from a system with water changes or by filtering water through activated carbon. Food fish must undergo a 7-day withdrawal period after treatment before harvest.

Potassium Permanganate: Potassium permanganate (KMnO_4) is an INAD, and KMnO_4 is used as an external parasiticide,

fungicide, and bactericide. It is a strong oxidizing agent and "burns" organic material off the external surface of fish. Overuse, particularly multiple uses within a short period of time (more than once a week) will kill fish. The concentration of KMnO_4 used varies with the permanganate demand of the water. In aquaria or ornamental ponds with very clear water, a concentration of 1–2 mg/L is usually safe and effective. Permanganate demand is greater in water with a high organic load. To determine the permanganate demand, a bioassay can be performed: the water to be treated is placed in small containers, and KMnO_4 is added in incremental concentrations of 2 mg/L. The correct concentration for therapeutic use will be the lowest concentration that maintains a pink color for 4–8 hr. If the concentration of KMnO_4 required is >6 mg/L, then the organic load is excessive, and sanitation practices should be evaluated. KMnO_4 has little impact on biofilters when applied at ≤ 2 mg/L. Potassium permanganate is more toxic as salinity of the water increases, and use in marine systems is not recommended. Food fish must undergo a 7-day withdrawal period after treatment before harvest.

Diquat: Diquat (Reward®), first registered as a contact herbicide (pesticide), has been used for many years to control columnaris disease (*F. columnare*) in fish. Only recently has it come under greater FDA scrutiny and become an INAD for control of *Flavobacterium* species associated with bacterial gill disease and columnaris disease. Withdrawal times for harvestable food fish species are 5 days for channel catfish, muskellunge, tiger muskellunge, and northern pike, and 30 days for all other fish species.

Diflubenzuron: Diflubenzuron (Dimilin®), a chitinase inhibitor used to control crustacean parasites, is a restricted use pesticide that can be applied only by licensed pesticide applicators. Dimilin is labeled for control of anchorworms on ornamental fish and baitfish commercially produced in ponds and tanks. Fish being raised for human consumption should not be exposed to diflubenzuron.

Anesthetics/Sedatives

Tricaine Methanesulfonate (MS-222, TMS): Tricaine methanesulfonate (approved product Tricaine-S®) is a benzocaine derivative and is the only FDA-approved fish anesthetic. TMS is approved for the temporary immobiliza-

tion of fish, amphibians, and other aquatic, cold-blooded animals. In fish intended for human consumption, TMS can only be used in members of the Ictaluridae, Salmonidae, Esocidae, and Percidae, and water temperature should not exceed 10°C (50°F). Withdrawal period if used in these species is 21 days.

Eugenol: Eugenol (Aqui-S20E®, active ingredient 10% eugenol), one component of several found naturally in clove oil, is an INAD intended for use as an anesthetic/sedative. Although eugenol is not approved, it is currently allowed for use in freshwater fisheries work as a zero-withdrawal fish anesthetic. However, if used in aquaculture, the withdrawal time is 72 hr. A related compound, isoeugenol (Aqui-S®), is not allowed for use in the USA because of carcinogenicity concerns.

Metomidate: Metomidate hydrochloride (Aquacalm®) is a fish sedative on the FDA-CVM *Index of Legally Marketed Unapproved New Animal Drugs for Minor Species* (the *Index*), labeled for the sedation and anesthesia of ornamental finfish. It is not legal for use in food fish species.

Spawning Compounds

Chorionic Gonadotropin: Chorionic gonadotropin (Chorulon®) is FDA approved for use as an aid to improve spawning function in male and female brood finfish. This is the only spawning aid approved by the FDA for use in food fish species. There is no withdrawal time if used according to label instructions on broodfish. Veterinarians may work as part of a team for fish hatcheries and may be asked to help obtain spawning hormones. Chorionic gonadotropin is a prescription drug and is restricted to use by or on the order of a licensed veterinarian.

Gonadotropin-releasing Hormone (sGnRHa) + Domperidone: Salmonid GnRH analogue + domperidone (Ovaprim®) is on the *Index* and labeled for use as a spawning aid in ornamental finfish broodstock. This product cannot be used in food fish species.

INFECTIOUS DISEASES

Some fish pathogens may be more common in or adapted to a given species, genus, or family; however, many are ubiquitous and have broad host ranges. Environmental factors, including type of rearing system and

production method, influence pathogen variety and prevalence within a given unit and facility. Many pathogens can infect fish regardless of rearing system and production method, but the following sections describe pathogens that may be more problematic under certain conditions.

Ponds: Most production ponds are outdoor and earthen (dirt or clay lined) and, over time, become high in organic loading as a consequence of feeding, fish growth, waste accumulation, and other related processes. In Florida, smaller ponds facilitate periodic cleaning, whereas much larger catfish ponds in the southeast are logistically much more difficult to clean. Although fish in production ponds are certainly susceptible to a wide spectrum of parasites, high organics favor sessile ciliates, including *Heteropolaria/Epistylis*, *Apiosoma*, and *Ambiphyra*, which attach to fish but feed on bacteria and other nutrients in the water column. Other protist parasites that thrive in rich, organic environments include the trichodinids (eg, *Trichodina*, *Tripartiella*), and *Tetrahymena*. *Uronema*, the marine counterpart to *Tetrahymena*, also thrives in highly organic waters.

Fish cultured in outdoor ponds are much more susceptible to infection by metazoan parasites with indirect life cycles because of the presence of final hosts and intermediate hosts that permit completion of the life cycle. These include digeneans, myxozoa, nematodes, and cestodes. The presence of birds and snails facilitate infestations by digeneans, requiring fish and snails as intermediate hosts and aquatic birds as the final host. *Bolbophorus damnificus* is an important digenean parasite of channel catfish, the final host of which is the American white pelican, and the intermediate hosts are the ram's horn snail and the fish. *Centrocestus formosanus*, another important digenean parasite infecting the gills of numerous fish species, uses a wading bird, such as the green heron or great egret, or the cone snail (*Melanoideis tuberculata*) to complete its life cycle.

Oligochaetes, annelid worms, are also much more prevalent in highly organic waters. *Henneguya ictaluri*, a myxozoan parasite and the causative agent of proliferative gill disease in channel catfish, requires the oligochaete *Dero digitata* to complete its life cycle. Eustrongylides, a nematode parasite that infects wading birds as adults, has an indirect life cycle that may involve either an oligochaete worm and a fish or just a fish. Juvenile, pond-reared fish can be

adversely affected when heavily infected with this organism. Other fish, reptiles, or amphibians may serve as paratenic hosts by feeding on infected fish and carry or transport the parasite.

Bacterial diseases, such as those caused by *Edwardsiella ictaluri* and *Streptococcus* spp, as well as viral diseases may be more difficult to control once they infect a pond population because of logistical challenges with pond disinfection.

Recirculating Aquaculture Systems:

Recirculating aquaculture systems (RASs), by contrast, are situated within enclosed facilities with more limited access by potential final or intermediate hosts. Parasites with direct life cycles are more common and dangerous in an RAS, because RASs used in production tend to have greater fish densities and by definition recycle water, which results in closer fish-to-fish contact and greater buildup of parasite numbers within the system. Once a parasite infects a fish within an RAS, it becomes magnified, and disease can spread rapidly. *Ichthyophthirius multifiliis* ("ich"), *Cryptocaryon irritans* ("salt water ich"), and *Amyloodinium* (marine velvet disease) can spread rapidly within an RAS. Similarly, egg-laying monogeneans such as *Dactylogyrus* sp and *Neobenedenia* sp, the capillary nematodes (which have direct life cycles), and microsporidia also can spread rapidly within an RAS.

Bacterial and viral diseases are also much more problematic in RASs, partly because microbial flora can be much less diverse and skewed than in more natural pond systems. Mycobacteriosis and streptococcosis have caused significant morbidity and mortality in RASs, which can favor their growth, amplification, and formation of reservoirs. Certain environmental conditions promote mycobacterial growth, including warm water temperatures, low dissolved oxygen levels, acidic pH, high soluble zinc, high fulvic acid, and high humic acid. Many of these conditions—especially the low dissolved oxygen, low pH, and an organically rich environment—are present in intensive aquaculture systems. Closed conditions and higher stocking densities enhance the potential for spread and amplification. Biofilms on the tanks, in pipework, and in filtration systems, as well as organics, inaccessible or overlooked mortalities, and detritus, can serve as reservoirs.

Net Pens/Cage Culture: Open ocean net pens, or cage culture systems within

large reservoirs or lakes, have their own unique challenges. Under ideal conditions, "open" access through the net or cage structures is intended to make use of the vast surrounding water body and allow for dilution of solid and dissolved wastes. However, this "open" access also facilitates direct or indirect contact with pathogens endemic to the water body. Smaller wild fish or other organisms may directly enter and intermingle with the farmed species, or pathogens themselves may flow directly into the structure through the water or on other vectors. The higher densities found in net pens and cages can then magnify the disease through close contact and facilitate spread.

Salmonid producers, during marine grow-out phases, can have significant losses caused by sea lice and infectious salmon anemia, among others. *Neobenedenia* and other monogeneans are a major problem in warmwater marine systems. Bacterial diseases such as vibriosis are common in net pens, and emerging viral diseases, including those caused by iridoviruses (including megalocytiviruses) and betanodaviruses, are of increasing concern in marine open ocean systems because of potential for transmission from wild populations.

PARASITIC DISEASES

Protists Infecting Gills and Skin: For information on protists infecting the gills and skin of fish, see p 1799. Information presented here is relevant to fish reared in intensively cultured systems. As previously mentioned, trichodinids are indicators of poor sanitation and/or overcrowding. These organisms are commonly found in cultured fish, especially in systems with high stocking densities, high organic loads, and minimal (or no) in-line sanitation (eg, UV or ozone). When fish are heavily infested, losses will occur. In these cases, chemical treatment alone may not be adequate for complete control. Addressing management problems that favor infestation should be incorporated into the treatment plan. Decreasing organic material is essential for treatment efficacy, because these organisms can be protected from chemical treatment by "hiding" within organic debris.

Ambiphyra and *Apiosoma* are sessile ciliates found on the skin, gills, and fins of fish. These are common in pond-reared fish and also have a predilection for organically rich environments. They are not generally found on marine fish. In high numbers,

these parasites can cause significant epithelial damage, predisposing fish to opportunistic pathogens in the environment and compromising respiration and osmoregulation. Infested fish demonstrate flashing, decreased appetite, loss of condition, and hyperplasia of infested epithelial surfaces. Severe infestation of the gills is particularly damaging. These organisms can be controlled with a single treatment of formalin, copper sulfate, potassium permanganate, or a salt dip. Excessive crowding and poor sanitation are frequently associated with heavy infestations and should be corrected.

For identification of protists affecting external surfaces of cultured fish, see p 1799. Control strategies are determined by the species affected and their intended use, the type of system the fish is housed in, cost of treatment, and environmental considerations.

Internal Protistan Parasites: For information on flagellated parasites (diplomonads such as *Spironucleus*, and kinetoplastids such as *Cryptobia rubilans*), see INTERNAL PROTISTAN PARASITES, p 1803. These parasites are also common in the GI tract of susceptible aquaculture species. The use of chemical treatment to control these organisms is not feasible in food fish; however, improvements in environmental conditions and husbandry will decrease morbidity and mortality.

Opalinids, larger "ciliate-like" parasites commonly found in the GI tract, may be found occasionally in kissing gourami, discus, some catfishes, and other species. Considered commensal by some, these may or may not be associated with disease.

Internal Metazoan Parasites: Myxosporean (Myxozoa) diseases significant in aquaculture include whirling disease and proliferative kidney disease (PKD) of salmonids and proliferative gill disease ("hamburger gill disease") of channel catfish. Whirling disease is caused by *Myxobolus cerebralis*. Fish are infected as fingerlings when the parasite infects cartilage in the vertebral column and skull, resulting in visible skeletal deformities. Affected fingerlings typically show rapid tail-chasing behavior (whirling) when startled. The disease is also sometimes called "blacktail," because the peduncle and tail may darken significantly. Recovered fish remain carriers. Adults do not show behavioral signs, but skeletal deformities associated with infection do not resolve. The disease can be prevented by purchasing uninfected

breeding stock and maintaining them in an environment free of the intermediate hosts (tubifex worms). A presumptive diagnosis of whirling disease is made by detection of spores from skulls of infected fish.

Diagnosis may be confirmed histologically or serologically. Whirling disease is of regulatory concern in some states.

PKD is one of the most economically important diseases affecting salmonid industries of North America and Europe. Rainbow trout are particularly susceptible. PKD is caused by *Tetracapsuloides bryosalmonae*, a myxosporidian with four distinct polar capsules. It occurs most commonly in the summer when water temperatures are $>12^{\circ}\text{C}$, and the parasite primarily infects yearling and younger fish. Clinical signs include lethargy, darkening, and fluid accumulation indicated by exophthalmos, ascites, and lateral body swelling. Infected fish are frequently anemic, resulting in gill pallor. Grossly, the posterior kidney appears gray, mottled, and significantly enlarged. Presumptive diagnosis can be based on observation of suspect organisms, 10–20 μm in diameter, in Giemsa-stained wet mounts of kidney tissue. Histologic examination of infected tissue, stained with H&E, and immunohistochemistry are required for confirmation. There is no treatment, but fish that recover from the infection are resistant to subsequent outbreaks. Infected stocks in nonendemic areas should be depopulated, the premises sanitized, and disease-free stock obtained for replacement. Avoidance is the best preventive measure.

Proliferative gill disease ("hamburger gill disease") is a myxosporean infection of channel catfish caused by *Aurantiactinomyxon ictaluri*. The organism has a complex life cycle, with the oligochaete worm *Dero digitata* serving as the intermediate host. Channel catfish may be aberrant hosts for *A. ictaluri*, and the disease usually occurs in new ponds or previously infected ponds that have been drained and refilled. Although proliferative gill disease can cause catastrophic mortality approaching 100%, losses may be as low as 1%. Disease occurs at water temperatures of $16^{\circ}\text{--}26^{\circ}\text{C}$, and mortality is exacerbated by poor water quality, particularly low dissolved oxygen or high levels of un-ionized ammonia. Gills of affected fish are severely swollen and bloody. A presumptive diagnosis can be made from a wet mount of infected tissue, in which filaments appear swollen, clubbed, and broken. Cartilaginous necrosis is strongly supportive of a diagnosis of proliferative gill disease;

however, histology is required for confirmation. Quantitative PCR has also been used diagnostically.

Platyhelminthes (Flatworms): Flatworms (Platyhelminthes: monogenea, digenea, leeches, turbellaria, *see* p 1807) are also of concern in aquaculture.

Monogeneans, including gyrodactylids, dactylogyrids, ancyrocephalids, and capsalids, have all been identified in numerous aquacultured species.

Gyrodactylus salaris is a reportable disease of salmonids but has not been reported in the USA. Any gyrodactylid found on a salmonid species should be identified well enough to determine whether it is *G. salaris*. *Neobenedenia* and *Benedenia* are important monogeneans in marine aquaculture.

Although treatments will vary depending on the aquaculture setting and species of parasite and fish host, formalin is approved for use in food fish. Hyposalinity for marine species, including freshwater dips, can help reduce loading on fish, but environmental reservoirs (eg, eggs) will need to be controlled as well. *Neobenedenia* was controlled in one study when salt levels were reduced to ≤ 15 g/L for 5 days and ≤ 18 g/L for 7 days. Hydrogen peroxide is not approved for use against monogenean infestations in food fish but can be used extra-label under the supervision of a veterinarian. Doses are experimental (*see Use of Hydrogen Peroxide in Finfish Aquaculture* [<http://edis.ifas.ufl.edu/fa157>] for some reported doses). Freshwater monogenea can be treated with formalin or saltwater dips to remove a majority of parasites from fish, but environmental stages (eg, eggs) will also require control.

Digeneans have complicated life cycles, with several larval stages that infect one or more hosts. As discussed above, fish raised in outdoor aquaculture systems are more likely to become infested by this group of parasites. With rare exceptions, the first intermediate host is a mollusc, without which the life cycle generally cannot be completed. The final host for many common freshwater aquacultured fish digenean parasites is a wading bird. A diagnosis usually can be established by gross or microscopic examinations that reveal the cercarial, metacercarial, or adult worms in any of the tissues or body cavities of the fish. Fish tend to form pigmented tissue encapsulations that encyst the parasites. Depending on the color of the cysts in the skin, the condition is called black, white, or yellow grub disease. Heavily parasitized fish

often are weak, thin, inactive, and feed poorly. In many cases, low level infestations may not result in significant morbidity but will prevent sale of fish for aesthetic reasons. Treatment is not recommended.

Pond-reared, juvenile, tropical fish may develop severe gill disease from metacercarial cysts of the digenea *Centrocestus formosanus* in gill tissue. Although acute death is occasionally seen, infected fish more commonly die during harvest or shipping when they may be exposed to suboptimal dissolved oxygen concentrations. If only a small percentage of gill tissue is infested, then fish may be clinically normal. Treatment of infected fish has not been successful; however, prevention of the disease by elimination of the intermediate host, the freshwater snail *Melanoides tuberculata* (common name, the red-rimmed melania), has been effective.

Bolbophorus confusus is a digenean trematode that causes morbidity and mortality in channel catfish fingerlings in production ponds in Mississippi, Louisiana, and Alabama. The definitive host of *B. confusus* is the white pelican, and the first intermediate host is the ram's horn snail (*Heliosoma* spp). Cercariae released from snails encyst in fish tissue, forming metacercariae in any tissue, but most are found in skin and skeletal muscle of the peduncle of juvenile channel catfish. Severe disease (mortality up to 95%) occurs when metacercariae encyst in visceral organs, particularly the posterior kidney and liver. Involvement of these organs can result in a presentation similar to that of enteric septicemia or channel virus disease, characterized by fluid accumulation in the abdomen and exophthalmia. Skin and muscle lesions typically result in raised bumps that are white to reddish in color. The presence of digenea in skeletal muscle can result in condemnation of affected carcasses by processing plants.

Other Vermiform Internal Parasites: **Acanthocephalids** (thorny-headed worms) are common in wild fish as both larval tissue stages and adult intestinal parasites. They are most common in salmonid and marine fish. Arthropods are the first intermediate host. Adult acanthocephala are easily recognized by their protrusible proboscis, armed with many recurrent hooks.

Pentastomids, which may present as either "white grub"-like lesions externally or within the body cavity in numerous organs, have been identified in aquacultured aquarium fish species, including swordtails. Fish are infected with the larval or "nymph"

stage, and the final hosts are aquatic reptiles (turtles, snakes, alligators). Under the microscope, pentastome nymphs appear as thick, stout, curved, and "segmented" worms (see *Pentastomid Infections in Fish* [<http://edis.ifas.ufl.edu/fa090>]). Fish often show no behavioral changes and may have minimal morbidity or mortality, but fish cannot be sold for aesthetic reasons. Treatment is not recommended, but management involves removal of final hosts from the system.

Crustacean Parasites: Crustacean parasites, including *Argulus*, *Lernaea*, and *Lepeophtheirus*, can become significant problems in aquaculture (see p 1808). Treatment of these organisms is not feasible for food fish species.

BACTERIAL DISEASES

Common Bacterial Pathogens (*Aeromonas*, *Vibrio*, and *Edwardsiella*): Common bacterial pathogens (see p 1808), *Aeromonas hydrophila*, *A. salmonicida*, *Vibrio* spp, *Edwardsiella ictaluri*, *E. tarda*, *Streptococcus* spp, and other related gram-positive cocci, can also infect aquaculture species. Organisms that may have previously been identified as *E. tarda* have now been recognized as new organisms with biochemical characteristics very similar to those of *E. tarda*. Two new groups are also recognized, *E. piscicida* and *E. piscicida*-like bacteria, which have been associated with disease in channel catfish and freshwater game fish (see below). Treatments for food fish species are limited to the species and disease indicated on the label of approved drugs, although approved forms of oxytetracycline and Romet® can be used extra-label under the supervision of a veterinarian. Florfenicol (Aquaflor®) is the only drug approved for use against streptococcal infections in freshwater-reared, warmwater finfish; however, extra-label use of this product is prohibited. Enrollment in an INAD program may allow limited use of florfenicol for indications and species beyond the current label. See <https://srac.tamu.edu/index.cfm/event/viewAllSheets/>, SRAC 4709 (Investigational New Animal Drug [INAD] Exemptions and the National INAD Program [NIP]). Appropriate withdrawal periods before harvest must be followed when used in food fish species (see TABLE 1, p 1750). Vaccines are available for a number of bacterial pathogens and species indications. Under supervision by a veterinarian, licensed

commercial vaccines can be used off-label (see *Use of Vaccines in Finfish Aquaculture* [<http://edis.ifas.ufl.edu/pdf/files/fa/fa15600.pdf>]).

Yersiniosis: Yersiniosis (enteric redmouth disease) is a serious acute or chronic bacterial disease of intensively cultured salmonids. The etiologic agent is *Yersinia ruckeri*. Signs are darkening and hemorrhage of the mouth (red mouth), skin, anus, and fins. Chronic signs are associated with inappetence, exophthalmos, swelling, and degenerative changes of internal organs. Mortality rates are variable but are exacerbated by poor water quality and related stressors. Diagnosis is by isolation and identification of pure cultures of the organism obtained from the internal organs of infected fish. Fish that survive remain carriers and may cyclically shed bacteria, particularly when exposed to stressful conditions and water temperatures of 15°–18°C. Depopulation of infected fish and avoidance of introduction of infected fish can be recommended, but preventive vaccination is the usual procedure in endemic areas. Yersiniosis can be treated successfully with antibiotics, which should be selected based on a sensitivity test. Therapy should be continued for at least 14 days.

Edwardsiella piscicida and E piscicida-like Diseases:

Edwardsiella piscicida causes **enteric septicemia of catfish**, the most important infectious disease in the channel catfish industry. Infection occurs in the spring and fall when water temperatures are 22°–28°C, and mortality may be exacerbated by handling stress, chemical treatment, or poor water quality. The disease occurs in two forms: the enteric (or intestinal) form and the meningeal form. In the enteric form, infected fish may develop skin lesions characterized by massive petechial hemorrhage around the mouth, operculum, and eyes, or they may develop measles-like, red, punctate lesions along the body wall. There is a hemorrhagic enteritis, and the intestine may be hemorrhagic and fluid- or gas-filled. Liver lesions are common and may be evident as multifocal areas of necrosis, abscessation, or hemorrhage. In contrast, in the meningeal form, few external signs may be seen in infected fish. The bacteria enter the CNS through the olfactory system, and affected fish develop severe meningitis. In fingerlings, the inflammation may be severe enough to erode the skull, resulting in the characteristic

“hole-in-the-head” lesion. Fish affected with the meningeal form may demonstrate bizarre behavior, including spinning, erratic swimming, and general disorientation. Diagnosis is based on bacterial culture and isolation. Brain culture is indicated whenever *E. ictaluri* is suspected. *E. ictaluri* will grow on blood agar incubated at 25°C for 48 hr. Antibiotic therapy should be based on results of sensitivity testing. Vaccination is available for channel catfish fingerlings.

There has been a significant change in understanding of fish diseases caused by an organism historically identified as *E. tarda*. This organism is the causative agent of **emphsematous putrifactive disease of catfish**. The name is descriptive of the most common lesions, an ulcerative dermatitis associated with a malodorous, gas-producing bacteria. *E. tarda* is an enteric bacterium that is ubiquitous in terrestrial and aquatic environments. It has been associated with enteric disease in manunals, including people, as well as birds, reptiles, and fish. Recent molecular work has demonstrated that several different organisms that may have been previously identified as *E. tarda* are likely causing many of the disease outbreaks attributed to *E. tarda* in fish. These newly recognized taxa, *E. piscicida* and *E. piscicida*-like organisms, are considered important emerging diseases in the channel catfish industry. They can present not only as an ulcerative dermatitis but also can cause a systemic granulomatous disease with gross and microscopic lesions very similar to those seen in mycobacteriosis (see p 1760). Granulomatous disease attributed to *E. piscicida* tends to result in hepatic lesions, which are not typical of mycobacteriosis. Histologically, the granulomas contain gram-negative and acid-fast negative rods. Molecular testing is required to confirm a diagnosis of *E. piscicida* or *E. piscicida*-like infection. The disease will respond to antibiotics, but it is unclear whether fish can clear bacteria sequestered in granulomas. These environmental bacteria thrive in organically rich environments, so sanitation may need to be addressed as part of the management strategy. For aquariums and recirculating systems, UV filtration may help decrease numbers of bacteria in the environment.

Columnaris and Related Diseases:

The taxonomic grouping of bacteria causing columnaris disease, coldwater disease, and bacterial gill disease has undergone significant revision in recent years based on

genomic studies. The primary causative agent of each of these important diseases has been moved into the genus *Flavobacterium*, although other genera have also been implicated. These gram-negative, rod or filamentous bacteria have a distinctive gliding motion. Skin or gill lesions have slimy or cotton-like surface exudates, which usually cover surface necrosis, ulcerations, and marginal hemorrhages.

Flavobacterium columnare, the most prominent member of this group responsible for **columnaris disease**, is most common in warmwater species of fish. A presumptive diagnosis can be made from visualization of typical organisms on wet mounts of infected skin or gill tissue. Columnaris disease can be confirmed by isolation of the organism on Ordal's or other cytophaga media. Sensitivity tests are difficult to perform, because *F. columnare* will not grow on Müller-Hinton media. If the disease is diagnosed early in the course of infection, treatment with potassium permanganate or hydrogen peroxide may be effective. If the disease becomes chronic, it may have become systemic, in which case treatment with florfenicol or oxytetracycline is recommended. Columnaris disease can be prevented by reducing organic loading and avoiding traumatic injuries. A vaccine is currently available in the USA for use in channel catfish and largemouth bass.

A similar organism affecting marine fish was previously grouped with *F. columnare* but has been given its own genus and is now named *Tenacibaculum maritimum*. Potassium permanganate may not be a good option in warmwater marine finfish because of its increased toxicity at higher salinities.

Flavobacterium psychrophilum causes **coldwater (peduncle) disease**, or bacterial coldwater disease, in salmonids and other coldwater species. Rarely, warmwater fish exposed to cold temperatures

may be affected. Disease is most severe at water temperatures of 4°–10°C, and signs should not be seen at temperatures >18°C. Skin lesions usually begin on the dorsal and posterior surfaces of the fish but may be found on any part of the body. Advanced cases show necrosis and ulceration of the peduncle, and underlying musculature will be exposed. As the disease progresses, the infection becomes systemic, typically involving the spleen, kidney, and liver. Confirmed diagnosis is possible after isolation of *F. psychrophilum* using cytophaga media (15°–20°C for 3–6 days), or by immunohistochemistry or PCR. Outbreaks can be controlled with oxytetracycline.

Bacterial gill disease, caused by *F. branchiophilum*, is most frequently reported in young cultured salmonids or fish cultured under conditions of high organic loading. It has been seen occasionally in aquarium fish. It may be initiated by crowding and poor water quality, particularly high organic loads, high ammonia levels, and silt. Gills appear swollen and mottled, with patchy areas of bacterial growth that can be confirmed by microscopic examination of direct gill smears. Hyperplasia, adhesions, and deformity of the gill lamellae can be seen. In young fish affected with the disease, mortality is high and morbidity sustained. Prevention efforts include improving water quality and avoiding overstocking. A single treatment with potassium permanganate, followed by addition of salt to the system (2–5 ppt) may help control losses, but sanitation is critical for longterm resolution of the problem. Antibiotic therapy may be used as needed to control secondary bacterial problems.

Bacterial Kidney Disease: Bacterial kidney disease is economically important in cultured salmonids. The cause is *Renibacterium salmoninarum*, an obligate intracellular bacteria that is one of the relatively few gram-positive organisms that causes disease in fish. Bacterial kidney disease is a chronic disease affecting juveniles (6–12 mo old) and prespawning adults, with clinical signs very similar to those of mycobacteriosis. Clinically, infected fish appear lethargic and darkened and may have coelomic distention, pale gills (anemia), and vent hemorrhages. Typical lesions include grayish, localized, or conglomerate granulomata in the viscera, especially the kidney or body wall; exophthalmos; blindness; cystic cavities in musculature; and emaciation. A presumptive diagnosis can be based on visualization of small, gram-positive rods

Erosion typical of columnaris disease in a silver dollar. Courtesy of Dr. Ruth Francis-Floyd.

in kidney imprints. Definitive diagnosis requires isolation and identification of the bacteria by using a selective medium that contains cysteine and incubating at 15°C for 3–6 wk. *R. salmoninarum* is transmitted both horizontally and vertically, and fish that survive an epizootic remain carriers. Infected female fish should be injected with erythromycin (11–20 mg/kg, IM) 14–60 days before spawning to prevent vertical transmission. Erythromycin (100 mg/kg for 10–21 days) is effective when administered in feed early in the course of an outbreak; however, it is not FDA approved for this use. Obtaining disease-free stock and preventing contamination by infected wild fish are the best preventive measures.

Mycobacteriosis: Mycobacteriosis (see also p 1810) is an important disease in aquaculture because of its typically chronic nature (although acute and subacute presentations can occur) and the lack of effective antibiotics. External or internal masses, nodules, or granulomas are a common presentation in aquaculture species. Important differential diagnoses for a suspect case of mycobacteriosis, based on identification of granulomas in tissue, are *Edwardsiella piscicida* (see p 1758) and francisellosis (see below). Further, although granulomatous lesions are typical of mycobacteriosis, they are not always seen. In some species, and under some conditions, granulomas may not be present. Instead, caseous (“pus-like”) lesions may be seen, or histologically, only a histiocytic inflammatory response (increased macrophages/tissue phagocytes without granuloma formation) may be apparent. Acid-fast stains and/or culture are necessary to exclude mycobacteriosis in cases with chronic morbidity/mortality and chronic inflammation but no granulomas. In addition, processing differences (including the decalcification method, if necessary, and the type of acid-fast stain used) may affect staining characteristics of mycobacteria.

Rickettsia and Rickettsial-like

Diseases: Rickettsial disease associated with *Piscirickettsia salmonis* has been described in salmonid species from Chile, Norway, Ireland, and Canada. Rickettsial-like organisms have been reported in tilapia, sea bass, and blue-eyed plecostomus. Rickettsial disease can result in acute mortality, affecting up to 95% of fish with few gross signs. In tilapia, acute mortality may be triggered by sudden drops in temperature. Chronic disease is manifest by nonspecific external lesions, including

anorexia, pale gills, and skin lesions. Internally, lesions are more typical, with granulomatous lesions possible throughout the viscera. The most characteristic lesions may be found in liver and kidney tissue and appear as gray to yellow mottled areas with ring-shaped foci. Visceral lesions are grossly similar to those seen in advanced cases of mycobacteriosis, and differentiation is important. Histologically, intracellular organisms may be seen in macrophages and hematopoietic tissue in the liver, spleen, and kidney. Blood or tissue smears stained with Giemsa or acridine orange may reveal the intracellular organisms, often appearing as paired, curved, gram-negative rods in macrophages or hepatocytes. *Rickettsia*-like organisms can be isolated using a variety of cell lines; however, confirmation of a suspect case may also be based on serology.

Transmission of rickettsial-like diseases in fish is not understood. In terrestrial species, a vector is often required; however, *R. salmonis* has been demonstrated to survive for 14 days in seawater, suggesting that horizontal transmission in the absence of vectors may be possible in aquatic species. Oxytetracycline is the treatment of choice, although it is unclear whether an advanced case can be completely resolved with antibiotic treatment. *Rickettsia*-like organisms do not appear to be a zoonotic threat, because they do not seem able to survive at mammalian body temperatures.

Francisellosis: Francisellosis, an important emerging bacterial disease caused by *Francisella noatunensis*, has been identified as the primary cause of disease in a variety of aquacultured and wild-caught species, including tilapia, hybrid striped bass, Atlantic cod, Atlantic salmon, various grunt species, ornamental cichlids, fairy wrasses, and blue-green damselfish. In tilapia, francisellosis is often associated with environmental stressors, especially cooler temperatures and poor water quality, and so increasing temperatures (for indoor facilities) may help mitigate the disease. Many signs and necropsy findings are grossly similar to those seen in mycobacteriosis. The disease can be acute, with few clinical signs and high mortality, or subacute to chronic, with fish demonstrating erratic swimming, spiraling, buoyancy control problems, anorexia, lethargy, exophthalmia, anemia, petechiation, and darkening. Severely infected fish may have necrotic or nodular gills with red and white patchiness, and

histologically, portions of the gill may also be severely hyperplastic with consolidation of secondary lamellae. On necropsy, the spleen and kidney typically have a granular or nodular (granulomatous) appearance, and most other organs can also be affected. Francisellosis should be another differential diagnosis for granulomatous disease in fish. Identification is supported by history, clinical signs, species affected, and presence of non-acid-fast bacterial organisms that are Giemsa positive and weakly gram negative. Because *Francisella* does not grow on routinely used media (such as blood agar), confirmation requires PCR of affected tissue and/or culture on various special media, all of which include increased levels of cysteine (or cystine) and glucose. Culture and sensitivity should be performed by a microbiologist and laboratory with expertise in this pathogen for identification and to determine sensitivity patterns. Because *Francisella* is intracellular and causes granulomatous disease, chemotherapy may be less effective, unless the disease outbreak is identified very early in its course. Optimization of husbandry, including increasing temperatures when possible, may help reduce morbidity and mortality.

MYCOTIC DISEASES

The “fungi” and “fungi-like organisms” (see p 1811) can affect aquacultured species. A number of these pathogens, previously lumped together as “fungi” based on similarity in morphology and saprophytic lifestyle, are unrelated taxonomically. The more common “water molds,” including *Saprolegnia* and *Aphanomyces*, are not true fungi but members of the Oomycota (Oomycetes). This distinction is important, because a more precise understanding of the biology of each group should lead to more targeted, effective management and chemotherapy.

Another true pigmented fungus, *Veronaea botryosa*, has been identified and described as the cause of a phaeohyphomycosis in aquacultured white sturgeon and Siberian sturgeon. Affected fish had one or more of the following clinical signs: abnormal orientation, buoyancy control problems, coelomic distention, reddening of the skin, emaciation, and ulceration of the skin or eye. Internal pathology included hemorrhages throughout the coelom, the presence of serosanguineous fluid, and organomegaly with nodules or cysts in multiple organs. Wet mounts of affected tissues often revealed presence of fungal

hyphae, and positive confirmation was based on culture characteristics and identification by PCR. The disease appears to be linked to environmental stressors that may include temperature.

In general, systemic fungal infections in aquacultured species do not respond well to treatments. External infections of *Saprolegnia* may require environmental/handling modifications in addition to chemotherapy. For food fish use, specific commercial formalin and hydrogen peroxide products are FDA approved for use against fungus on fish eggs. Use of these products on other life stages is extra-label and requires veterinary oversight.

Mycotoxins: See also p 1811. As in other species, mycotoxin contamination of feeds is associated with disease in aquaculture species. Specifically, exposure to aflatoxin-contaminated feed causes serious disease in rainbow trout. Aflatoxin is produced by fungi in the genus *Aspergillus* and is commonly associated with use of oil-seed crops such as corn, cottonseed meal, and peanuts. Toxin production may be associated with improper storage, with high humidity (>14%) and high temperatures (>27°C) being significant risk factors. Affected trout may have a grossly distended abdomen, and necropsy findings reveal a hepatoma or hepatic carcinoma. Liver lesions have been reported after exposure to concentrations as little as 1 mg/kg. Disease has been induced experimentally in tilapia at higher concentrations and/or extended exposure periods. In one study, tilapia fed 10 mg/kg for 8 wk had liver pathology and when fed 100 mg/kg for 8 wk, hepatic necrosis and mortalities were seen. In another study, tilapia fed 0.245 mg/kg over the course of 20 wk demonstrated reduced growth and liver pathology. Presence of the toxin can be confirmed using high-performance liquid chromatography (HPLC) or ELISA. Commercial test kits are also available.

VIRAL DISEASES

The identification and characterization of previously undescribed viral diseases in aquaculture is increasing because of recent technologic advances and increasing expertise in the aquatic veterinary field. Viruses (see p 1812) may also affect susceptible species in aquaculture settings. Again, management options are limited but vary depending on the type and pathogenicity of the virus, species susceptibility, reportability, and whether the virus is

considered endemic or exotic. In general, no approved or effective treatments exist for viral diseases in aquaculture species. Temperature manipulations are problematic, especially because of concerns over latency and potential recrudescence. Vaccine development for economically important viruses is ongoing, and some vaccines exist for some viruses either in the USA or internationally. Additional viruses of importance to aquaculture are described below.

Herpesviruses (Alloherpesviruses)

Herpesviruses (alloherpesviruses) are also important pathogens in aquaculture (see also p 1812). Herpesviruses have been isolated in a number of different aquacultured species, including cyprinids and various cichlid species.

Channel Catfish Virus Disease:

Channel catfish virus (CCV) disease is an acute, virulent herpesvirus infection of fry and fingerling channel catfish that can cause mortality of >80% at water temperatures $\geq 25^{\circ}\text{C}$ in small fish (≤ 5 cm). As fish age, mortality decreases, and clinical infection in fish >1 yr old is rare. Acute infection often includes a recent history of a stressful event such as handling or transport, low dissolved oxygen, or chemical treatment. Infected fish show signs of ascites, exophthalmos, and hemorrhages in fins. The cell line of choice for virus isolation is channel catfish ovary, followed by serum neutralization to confirm identification. Typical cytopathic effects include cell fusion, syncytia formation, and intranuclear inclusions. There is evidence for vertical transmission of CCV; consequently, survivors of an epizootic should not be used for broodstock. Although CCV can cause severe mortality when an outbreak is in progress, the annual number of cases of CCV in the catfish industry is relatively low.

Novirhabdoviruses

Infectious Hematopoietic Necrosis:

Caused by a novirhabdovirus in the family Rhabdoviridae, infectious hematopoietic necrosis is listed as a $\bullet$ IE notifiable disease. It is endemic in salmonid (*Oncorhynchus* spp) populations in the Pacific Northwest and Alaska and has been reported in Atlantic, chum, chinook, sockeye, and kokanee salmon and in cutthroat, steelhead, and rainbow trout. Lake trout and Arctic char, members of the genus *Salvelinus*, appear resistant. The disease has also been reported in parts of Europe and Asia. Most

epizootics have been attributed to importation of infected eggs or fry.

Acute disease in fry <2 mo old may result in high mortality (>90%) with few external signs. Disease usually occurs at water temperatures of 10° – 12°C , although outbreaks occasionally occur at temperatures $>15^{\circ}\text{C}$. Typical signs include lethargy with sporadic hyperexcitability, including whirling. Sick fish may be darkened with distended abdomens, exophthalmia, pale gills, and mucoid fecal casts. Important differential diagnoses include infectious pancreatic necrosis and viral hemorrhagic septicemia. Hematopoietic tissue in the kidney and spleen are most severely affected by necrosis.

Risk factors include age (fish <2 mo old are more susceptible), density, and water temperature. Hauling young fish around dams in trucks may be a significant risk factor because of crowding during transit. Although most disease outbreaks have been reported in freshwater, active disease has occurred in Atlantic salmon housed in sea cages. Diagnosis is by viral isolation (from kidney and spleen of young fish and ovarian fluid of broodstock), with confirmation by serum neutralization. Rapid serologic tests are becoming more available. A nonlethal test involving viral isolation from mucus has been reported. The disease is transmitted horizontally through the water, and vertical transmission is suspected. Asymptomatic carrier fish serve as reservoirs of infection. A vaccine is available in the USA for use against this pathogen.

Viral Hemorrhagic Septicemia: Viral hemorrhagic septicemia (VHS) is caused by a novirhabdovirus in the family Rhabdoviridae and is a highly regulated disease in the USA. VHS can be divided into several different strains based on genotype: VHS strain IVa is the predominant strain in USA aquaculture; strain IVb (see below) has been identified in wild stocks only in the USA and Canada; and strains I, II, and III are found primarily in Europe and Asia. The disease causes marked necrosis of hematopoietic tissue in the kidney, particularly the anterior kidney, but largely spares excretory tubules in the posterior kidney. Rainbow, brook, and lake trout (genus *Salvelinus*) and Atlantic salmon and brown and golden trout (genus *Salmo*) are susceptible. The virus also causes disease in a variety of freshwater and marine coldwater fish, including pike, turbot, white fish, and sea bass. VHS also is found in free-ranging marine fish in the Pacific northwest, including anadromous salmon (coho and chinook), as well as haddock and cod in the North Sea.

The disease occurs in three forms: acute, chronic, and nervous. Acute mortalities occur in rainbow trout fry <3 g and <30 days old. In these fish, the kidney is swollen and the anterior segment is necrotic and pale. The liver may be pale with hemorrhagic mottling, and systemic hemorrhage may be visible in the eyes, skin, skeletal muscle, and viscera. The most notable lesion is widespread hemorrhage in the liver, adipose tissue, and within skeletal muscle. Moribund fish lie on the bottom of the tank and may exhibit sporadic flashing and corkscrew swimming behavior. As fish age, mortalities drop from 80%–100% to 10%–50%. The chronic form is a persistent infection with low RBC and WBC counts; virus can be isolated from all tissues. Chronically infected fish may exhibit few visible external signs. The nervous form of the disease has been reported primarily in cultured freshwater fish but has also been reported in marine fish.

The optimal temperature for active infection is 9°–12°C; the virus is unable to replicate at temperatures >15°C. The cell line of choice for virus isolation is bluegill fry (BF-2). Viral identification is confirmed by serum neutralization. Newer diagnostic tests include immunofluorescence, ELISA, and PCR. VHS is a highly regulated disease, with disease-free geographic regions defined in Europe. No vaccine is commercially available. Veterinarians working with zoologic collections must ensure that susceptible species received from endemic areas are properly tested and certified disease free.

In 2005, a new strain of VHS, VHS IVb, was identified in the Great Lakes and caused widespread morbidity and mortality of only wild stocks. Affected species included muskellunge, Chinook salmon, brown trout, freshwater drum, black crappie, bluntnose minnow, gizzard shad, largemouth bass, smallmouth bass, blue gill, yellow perch, and channel catfish. Signs of VHS IVb can be nonspecific. Some affected fish have no clinical signs, but exophthalmia, ascites, hemorrhages (in the eyes, skin, gills, fin base), and behavioral changes may be seen.

To date, no aquacultured specimens have been found to be infected with this strain, but veterinarians should be aware of it and avoid introducing stocks or water from infected/unprotected systems.

Iridoviruses

Viral Erythrocytic Necrosis: Viral erythrocytic necrosis has been reported in >20 species of marine and anadromous fish (both cultured and free ranging) and is

characterized by erythrocytic degeneration. Affected species include Pacific herring, Atlantic cod, and Pacific salmonids (chum, pink, coho, and Chinook), steelhead trout, and cultured eels in Taiwan. The disease is chronic, and external signs may be subtle or nonexistent. Sick fish are anemic, which may result in pale gills and internal organs. Severity of the disease is related to age and species of fish, with juveniles <1 g most severely affected.

The characteristic lesion is a single eosinophilic cytoplasmic inclusion body in the circulating erythrocytes of anemic fish. The inclusions are best visualized from Giemsa-stained fresh blood smears. To date, the agent has not been successfully isolated. Histologically, increased hematopoietic activity may be evident in the kidney, and round cytoplasmic inclusions (0.8–4 µm) are found in circulating RBCs. Inclusions stain pink or magenta with Giemsa. Other degenerative changes may be evident in RBCs, including cytoplasmic vacuolation and margination of nuclear chromatin. Hemolytic anemia with concurrent hemosiderosis and erythroblastosis has been reported in moribund Pacific herring. Multinucleated giant erythroblasts may occasionally be seen in peripheral blood, and macrophages may phagocytize abnormal erythroblasts. A presumptive diagnosis is based on the presence of typical cytoplasmic inclusions in circulating RBCs of anemic fish. Confirmation requires visualization of hexagonal virus particles in cytoplasm of affected RBCs using transmission electron microscopy. A marine reservoir is suspected but has not been identified. Vertical transmission is suspected because of the high prevalence of infection in fry from infected broodstock.

Epizootic Hematopoietic Necrosis:

The ranaviruses are an important group within the family Iridoviridae and, as a group, include viruses that can infect fish, amphibians, and reptiles. One of these causes epizootic hematopoietic necrosis (EHN), which so far has been reported to cause disease only in fish and is listed as a notifiable disease by OIE. First reported in redfin perch in Australia in the spring of 1984, it has since been shown to cause disease, albeit less severe, in rainbow trout. Similar viruses have been reported in sheatfish in Germany and black bullhead catfish in France and Italy.

EHN is endotheliotropic, producing necrotic lesions in the endothelium of blood vessels and some visceral lesions. Behavioral signs include lethargy, darkening,

and erratic swimming. Mortality occurs after 4–5 days. The most consistent lesion associated with EHN is focal necrosis of hematopoietic tissue in the anterior kidney and liver. Necrotic hematopoietic cells may be visible within blood vessels. Presumptive diagnosis is based on clinical signs and isolation of the suspect agent in cell culture. Bluegill fry (BF-2) is the cell line of choice. Detection may also be accomplished using ELISA, immunofluorescence, or electron microscopy. Epizootics of EHN in redfin perch are most common in the spring and summer and almost exclusively involve juvenile fish. Survivors seem to be resistant to future infection. There is no evidence of vertical transmission of EHN, and redfin perch carriers have not been detected. An unidentified reservoir and carrier host is suspected. Fomite transmission of EHN has been demonstrated, and birds have also been shown to carry infected material.

Largemouth Bass Virus: This ranavirus was isolated from moribund largemouth bass in South Carolina in 1995. It was previously isolated from largemouth bass in several Florida lakes but had not been directly associated with disease. It has been found in largemouth bass in most southeastern and many midwestern states. The disease is not well understood, because the virus is commonly isolated from tissues of clinically normal fish. In the 1995 fish kill, ~1,000 fish died over a 2- to 3-mo period in an area that encompassed >66,000 hectares. Lesions were nonspecific and are still poorly described. Fat-head minnow (FHM) is the cell line of choice for isolation of virus.

Megalocytiviruses: The megalocytiviruses are another very important and emerging group of viruses within the family Iridoviridae (see MEGALOCYTVIRUSES, p 1814). They have been associated with disease in freshwater angelfish and gourami species, as well as in numerous other aquacultured freshwater and marine food and aquarium fishes, including oscars and other cichlids (family Cichlidae), swordtails, sailfin mollies, and other common live-bearers (family Poeciliidae), and Banggai cardinalfish. Numerous marine and freshwater food and game finfish species are also naturally susceptible to infection by megalocytiviruses, including jacks and pompanos (several species, family Carangidae), mackerels and tuna (several species, family Scombridae), grouper (several species, family Serranidae), cobia (*Rachycentron canadum*), largemouth bass (*Micropterus salmoides*),

barramundi (*Lates calcarifer*), redbass (*Sciaenops ocellatus*), hybrid striped bass (*Morone saxatilis* × *M. chrysops*), and gray mullet (*Mugil cephalus*).

Clinical signs are nonspecific but include lethargy, anorexia, darkening, abnormal swimming (including spinning) or position in the water, increased respiration, coelomic distention, ulceration, hemorrhages/petechiae, pale gills/anemia, fin erosion, white feces, and moderate to heavy mortalities. Higher temperatures may be associated with some outbreaks.

Diagnosis is based on clinical signs, history, histopathology, and PCR identification (many of these viruses have not been successfully cultured). Histopathology often includes areas of acute, diffuse, severe coagulative necrosis in some tissues, and/or variable amounts of necrosis and mild inflammation. Large, finely granular basophilic to amphophilic intracytoplasmic inclusions are most commonly identified in spleen and kidney, although in severe infections, liver, heart, oral cavity, thymus, bone, gills, skeletal muscle, submucosa of the GI tract, and gonads are also affected.

There is currently no treatment for megalocytiviruses other than depopulation. A vaccine is available internationally but not yet available in the USA.

Other Viruses

Infectious Salmon Anemia: Infectious salmon anemia is reportable to USDA-APHIS and the OIE. The first report was from farmed Atlantic salmon on the west coast of Norway in 1984. Affected fish were lethargic and severely anemic (PCV <5% in moribund fish). The causative agent is an orthomyxovirus. Acute outbreaks result in high mortality. Initial signs include lethargic fish hanging around the edges of the cage. As the disease progresses, moribund fish lie on the bottom.

Diagnosis is based on clinical signs, with emphasis on anemia (PCV <10%), the gross appearance of a dark liver, and hepatic necrosis. Confirmation can be by viral isolation using the SHK-1 cell line. Virus may be visualized in endothelial cells of cardiac blood vessels using transmission electron microscopy. The agent is enveloped, slightly pleomorphic, and ~100 nm in size. Suspected cases can also be verified using an immunofluorescent antibody technique on frozen tissue. Transmission is horizontal, and virus is shed in skin, mucus, feces, and urine. Sea lice (*Lepeophtheirus salmonis*) may be a vector; disease outbreaks seem worse when sea lice are

present. There is no evidence of vertical transmission. Sea trout have been proposed as a possible reservoir of infection. Protective immunity has been demonstrated in salmon that survive an outbreak. Vaccines are available internationally but may not confer complete protection. The disease is heavily regulated in Norway and now in the USA, where the USDA should be notified immediately of any suspected cases.

Infectious Pancreatic Necrosis:

Infectious pancreatic necrosis is an acute, systemic, contagious disease of salmonid fry and fingerlings caused by a birnavirus. The virus is the archetype of the aquatic birnaviruses, which are further subdivided into two serotypes, A and B, that do not cross-react using serum neutralization. The serotype B group currently consists of only 10 isolates, all European in origin. In contrast, the A serotype contains >200 isolates that have been further subdivided into 9 serotypes, A1–A9. Morbidity and mortality occur only in young animals, usually <3 g; however, virus can be isolated from survivors for the duration of their lives, resulting in a persistent carrier state. Recrudescence of disease in survivors has not been reported. The virus is vertically and horizontally transmitted, widespread, and reported worldwide, except in Iceland and Australia. Rainbow trout are highly susceptible to disease. In the USA, striped bass and their hybrids are recognized as potential carriers. Other species affected include freshwater eels (*Anguilla* spp), yellowtail, turbot, sea bass, and menhaden, as well as aquatic invertebrates including molluscs and crustaceans. Brook trout are believed to be reservoirs of infection in the USA.

Clinical infection is nonspecific. Diseased fish may be anorectic, ataxic, and display a corkscrew swimming pattern. Externally, fish are darkened; exophthalmia and external petechiation may be evident. Internally, petechiae may be visible on viscera; the gut is typically empty and may contain a yellow exudate. Fecal pseudocysts may be evident in the water column. Histologically, focal areas of coagulative necrosis involve acinar and islet cells of the pancreas and hematopoietic cells of the kidney. Intracytoplasmic viral inclusions may be visible in pancreatic acinar cells. Infection should be confirmed with viral isolation followed by serum neutralization. Most fish cell lines are susceptible. The virus can also be identified using fluorescent antibody, complement fixation, and ELISA

techniques. There is no treatment for infected fish, but avoidance can be accomplished by purchase of SPF stocks, quarantine, and disinfection of eggs with iodophores (20–50 mg/L). Infectious pancreatic necrosis is not regulated by the USDA, but state regulations exist in various parts of the country.

Salmonid Alphaviruses: Salmonid alphaviruses are the cause of pancreas disease and sleeping disease in Atlantic salmon, rainbow trout, and brown trout. To date, reports have been from Norway and parts of the UK, although farmed fish in other countries in Europe have also been affected. This suite of diseases and the etiologic agent are reportable to USDA-APHIS and the OIE, and this disease is considered a foreign disease to the USA. As the disease names suggest, pathology involves necrosis and loss of exocrine pancreatic tissue, as well as changes in heart and skeletal muscle. Mortality rates vary from minimal to >50% in severe cases. As a sequela, a percentage of surviving fish may become slender and long runts. Survivors may also become carriers; however, vertical transmission is still under debate, and horizontal transmission is considered the main route of infection. A vaccine is available in affected countries.

Viral Nervous Necrosis (Betanodaviruses): The betanodaviruses are an emerging group of viruses infecting >40 different species of primarily marine fish worldwide. Susceptible species include red drum, cobia, barramundi, tuna, groupers, flatfishes, surgeonfishes, lemonpeel angelfish, the orbicularis batfish, and tilapia. The resulting disease is also known as viral nervous necrosis (VNN) and viral encephalopathy and retinopathy. A few freshwater species have also been reported as susceptible. Betanodaviruses can infect tropical, subtropical, or cold-temperate species, with species susceptibilities and optimal temperature ranges varying depending on the strain of the virus. Four different genotypes are currently recognized, and VNN is reportable to USDA-APHIS and the OIE. As a group, betanodaviruses can infect fish at temperatures ranging from approximately 15°–30°C.

Younger life stages (larvae, fry, fingerlings) are more frequently affected, although older, market-size fish may become affected. Losses can range from 15%–100%. Betanodaviruses are somewhat unique in that, as the disease name suggests, their target tissue is the CNS.

Consequently, clinical signs include abnormal swimming or spinning, vertical position in the water, flexing of the body, muscular tremors, and darkening or lightening of the skin. Hyperinflation of the swim bladder is also often seen, with affected fish positively buoyant and found near the surface. Traumatic lesions resulting from abnormal swimming may be secondary sequelae. Betanodaviruses can be spread horizontally and vertically, and live or frozen fish fed to broodstock or grow-out stages may be a potential source of infection. Other sources of infection

include wild invertebrates and contaminated water. Egg disinfection may help reduce impact of the disease. A commercial vaccine may be available internationally, but none is currently available in the USA.

Histopathologically, in properly fixed samples of affected CNS tissue (brain, spinal cord, retina of the eye), the presence of severe vacuolation is a hallmark of the disease. Disease and pathogen confirmation is based on clinical signs, species, histopathology, immunofluorescent antibody techniques, and PCR.

AQUATIC SYSTEMS

A fundamental assessment in working with aquatic species is examination and evaluation of the life support system sustaining the animals. This is a critical step in the clinical examination of any aquatic species, not just fish. The emphasis of this chapter is on aquarium and aquaculture systems, but the principles may be applied to life-support designs for all aquatic organisms.

Water quality management is a basic component of successful maintenance of aquatic organisms. Information is presented on normal parameters, as well as on environmental diseases of fish.

TYPES OF AQUATIC SYSTEMS

There are three basic types of aquatic systems, broadly defined as "open," "semi-open," or "closed." An open system has incoming water from some source (eg, surface water, well water, or city water) flowing through the culture facility one time, then discharged. Raceway and cage systems are examples of open systems. Semi-open systems have some capacity to recirculate water, which requires some type of treatment, but fresh water from an external source may be added as needed to supplement the treated water. Closed systems can be natural, such as static outdoor ponds, or can be highly engineered; intensive aquaculture systems depend on extensive filtration of water before recirculation. Aquariums are typically considered closed systems; however, the complexity of design and carrying capacity of individual systems vary greatly.

Basic housing units for fish may be outdoor ponds, raceways, cages, or aquarium systems (which may include recirculating system designs). The selection of a housing unit will be determined by available resources and facilities, as well as the goals of the owner.

Outdoor ponds are typically constructed in clay-based soils, or they may have a type of plastic liner to retain water. In Florida, there are also "water table ponds," which have a certain amount of horizontal flow of ground water into and out of the pond. Production ponds vary greatly in size, but a good design maximizes surface area while minimizing depth (ideally <6 ft). This design decreases the risk of stratification that can result in catastrophic "turnover" events (*see p 1771*). Ideally, an aeration device should be available for all outdoor ponds. In the southeastern USA, most aquaculture production ponds range from 0.1–20 surface acres of water, whereas recreational fishing ponds usually have a smaller surface area but may be quite deep, substantially increasing the risk of stratification and turnover.

Ornamental ponds may vary from a few hundred gallons to many thousands. Larger ponds (>10,000 gal.) are usually easier to manage from a water quality perspective and are more forgiving of an owner who may overstock or overfeed the fish. Most larger ponds have water provided from a well or city water source and are operated as closed systems. Supplemental aeration is also very important for these systems and is often provided by a waterfall, stream, or other aesthetic means of moving water.

Clinicians should not only test dissolved oxygen (DO) when evaluating an ornamental pond but also assess water movement. In poorly maintained systems, filters will become clogged and flow rates can decrease dramatically. Poor flow rates result in poor performance by biofilters and, ultimately, system failure with consequent rises in total ammonia nitrogen concentrations. Poor flow rates are also often associated with low levels of DO and an inability to maintain oxygen concentrations near saturation. If the pond depends on a waterfall as the primary source of aeration, and flow rates decline, the aeration capability is also compromised. Shade may be an important consideration when evaluating an ornamental pond. Lack of shade can result in rapid and extreme heating of water, especially if the pond is shallow. Hot water is not only detrimental in its own right, but it also does not hold oxygen well, increasing the risk of oxygen depletion. Shade trees around a koi pond may contribute to leaf litter and organics in the pond. Preventing predation is another important consideration when designing an ornamental pond. Typically, fish housed in these units are very colorful and may be very attractive to birds (including owls), as well as to mammalian predators such as raccoons or otters. In Florida, reptiles (eg, alligators) may also prey on ornamental fish. Some type of visual barrier to minimize the detection of colorful fish by birds can help, as can pond design features or other structures that limit the ability of wading birds to access the pond. An electric perimeter fence located 12–18 in. off the ground may keep small mammals or crocodilians out of an owner's yard, protecting the fish and other pets.

Other types of systems, more typical of aquaculture production, include cages and raceways. A raceway system is typically a series of long, narrow, and relatively shallow concrete or earthen tanks. Water enters the unit at one end and is discharged at another. Often, these use some source of surface water, such as a flowing river, for growout of the fish. Advantages of raceway systems include capacity for heavier stocking densities than ponds of a corresponding volume. Disadvantages include concerns about bringing pathogens or contaminants onto the farm and discharging nutrient waste, pathogens, or treatment chemicals in the effluent. Cage production is most common in open water, with the salmon industry being a prime example. Typically, large cages are placed in protected bays for the grow-out phase of the operation.

Alternatively, new technologies allow cage systems to be completely sunk in deep water, decreasing the risk of damage from wind and wave action. Advantages of cage production include tidal water exchange, which would not require pretreatment to be suitable for the fish. Disadvantages include potential damage to equipment or escape of fish during storms, potential contamination in the event of a chemical spill or harmful algal bloom, and concerns about adverse environmental impacts by the aquaculture operation itself. Global use of cage culture technology is increasingly important as marine food fish are cultured more intensively.

AQUATIC LIFE SUPPORT SYSTEM COMPONENTS

The basic components of a life support system are a vessel that houses the animals, and if water is to be recirculated, the filtration components, and a sump or reservoir (area to collect water before and/or after treatment). Understanding these component parts can help the practitioner appreciate the basic design and how it may impact animal health and disease management. Additional study is required for clinicians who plan to develop greater knowledge and skills for aquatic practice.

There are three basic types of filtration: biologic, mechanical, and chemical. All recirculating systems have biologic and mechanical components, and most also include a chemical component. Some types of filters provide more than one of these functions and may be dual purposed in the design. Practitioners should familiarize themselves with basic filtration and more complex system designs as their experience grows.

Biologic Filtration: Biologic filters remove nitrogenous waste from the system. Fish excrete ammonia directly from the bloodstream via passive diffusion across the gill epithelium. Biologic filters provide substrate and massive surface area for nitrifying bacteria to live. These bacteria are ubiquitous in the environment and grow well when nitrogenous compounds (ammonia and nitrite) are present in the water column. These bacteria require both oxygen and a carbonate source, which must be provided by the water and filter design. Examples of biologic filters are plastic plenums placed in the bottom of home aquaria, fluidized bed filters common in commercially designed systems, and an array of bead and sand filters sold for use in ornamental pond and aquaculture units.

Generic schematic of a basic aquatic life support system. Mechanical filtration should precede biofiltration. Mechanical filters help prevent channeling and anoxia in biofilters by removing large particulate matter. Biofilters must have a lot of surface area for nitrifying bacteria. Chemical filtration, although not required in all designs, polishes and cleans water before it is returned to the vessel housing the fish. *Courtesy of Dr. Ruth Francis-Floyd.*

Mechanical Filtration: Mechanical filters are always placed before biologic filters in the system design. Mechanical filters typically receive water leaving the vessel housing animals and remove large particulate matter before water comes into contact with the biofilter. Large particles can clog a biofilter, resulting in channeling and development of anoxic areas that greatly compromise function of the unit. Mechanical filters can be as simple as floss or foam pads receiving a stream of water, or much more complex. Sand and bead filters are commonly used and have dual functions of mechanical and biologic filtration.

Chemical Filtration: Chemical filters provide a way to treat the water. Activated carbon is very commonly used to remove toxins and colored compounds from aquarium water, which helps maintain clarity. Activated carbon filters may also be placed on inflowing water to remove chlorine and/or chloramine from city water. Activated carbon filters can also be used to remove treatment chemicals from water before discharge to city sewers. Other examples of chemical filters include protein skimmers and foam fractionators, which are commonly used in marine systems to remove proteinaceous waste (decreasing

the load on the biofilter); ultraviolet light, which removes potentially pathogenic organisms from the water column; and ozone, which clarifies water and kills microbes. Ozone is common in large commercial aquaria and requires a degassing area before the treated water comes back into contact with fish. Malfunction of ozone units can be hazardous to people as well as animals housed in aquarium systems.

EQUIPMENT NEEDED FOR SYSTEM AND WATER ANALYSIS

To competently assess a system's design takes some practice, but a basic understanding and analysis can be accomplished by keeping in mind the component parts and their functions. Site visits are essential to understanding how a system has been put together. In addition to assessing the design and functionality of a system, a site visit allows the opportunity to assess maintenance and cleanliness, both critical aspects of animal husbandry. The importance of a DO meter cannot be overstated when assessing an aquatic system. Oxygen concentration should be measured in the area housing the animals, and it should also be used to help identify areas prone to

anoxia because of equipment problems, poor maintenance, or design flaws.

Water quality testing equipment is a requirement for aquatic practice. Good quality testing kits are commercially available at reasonable prices. Tests can be run quickly, providing data in a timely manner. Basic requirements include a means to test temperature, DO, carbon dioxide (CO₂), chlorine, chloramine, ammonia, nitrite, nitrate, pH, total alkalinity, total hardness, and salinity. Testing for freshwater and marine systems is similar; however, the ammonia test often sold for freshwater use requires the use of Nessler's reagent, which has two distinct disadvantages: it contains mercury and therefore must be treated as hazardous waste, and it does not work in marine systems. Alternatively, an ammonia test using an ammonium salicylate reagent is recommended. Chlorine test kits (free and total chlorine) are not included in many kits marketed to the aquaculture industry and need to be ordered separately. Also, a copper test kit and a refractometer (to measure salinity) should be on hand for use in marine systems. If a practice has enough cases to warrant the investment, an electronic oxygen meter is strongly recommended. If working in a rural area where well water is commonly used, test kits for iron and hydrogen sulfide should be considered. For true specialty practices, investment in a satrometer for detection of supersaturation is also suggested.

ENVIRONMENTAL HISTORY

As with all aspects of medical analysis, a good history is critical in establishing a diagnosis. Specific questions are important to assess the environmental quality and may play an important role in treatment recommendations. First, a thorough description of animal housing should include the volume, design of the system, and source of water. The number and size of animals stocked, species (fish and non-fish), new additions, use of quarantine, decorations, plants, and previous medications are part of the case history and may also be relevant to assessment of environmental quality and system design. Owners can be asked to bring fish and water samples to the clinic, or the practitioner may wish to visit the site. Site visits allow the system to be more accurately evaluated and the behavior of fish to be readily observed. If a site visit is not possible, the owner can be asked to provide a video and/or photos of the system (including filtration) and the fish, both

affected and unaffected. If fish are brought into the clinic for examination, a separate water sample should be provided in a plastic bag or clean, plastic water bottle. If the source water is from a municipal water supply, a second sample should be collected in a glass bottle for chlorine/chloramine testing. Water samples collected by the owner should be capped under the surface of the water without any gas bubbles visible. A minimum of 1 quart of tank water should be requested for regular analysis, and a second smaller sample (<100 mL) in a glass container for chlorine testing. If desired to use for recovery after anesthesia of the animal, a larger volume of tank water may be requested.

ENVIRONMENTAL DISEASES

Because poor water quality is the most common cause of environmentally induced diseases, some way to assess water quality is essential. Inexpensive test kits are easy to use and provide reasonably accurate information. Professional aquaculturists or advanced tropical fish hobbyists should be encouraged to purchase and use their own water-testing equipment. Pet fish owners often rely on pet stores to do the water testing; however, many pet stores have very limited capabilities in this area, use less accurate tests, and may be unable to accurately interpret results.

Veterinarians practicing fish medicine should have a comprehensive understanding of the dynamics and management of water quality, including general guidelines for acceptable water quality parameters (see TABLE 2). In addition to temperature, basic parameters of water quality can be grouped into four major categories: dissolved gases, nitrogenous compounds, pH and carbonate compounds, and salinity. The significance of water quality parameters varies with the type of system, species, and stocking density. Low DO and high ammonia are the two water quality parameters most likely to directly kill fish. Water quality interactions are dynamic and complex. Indirect relationships can lead to toxicity from other parameters, such as the effect of rising pH on (increased) ammonia toxicity, or there can be indirect relationships between water quality and certain infectious agents. For example, low or inappropriate temperature can be associated with fungal diseases of fish. A classic example is *Fusarium solani* infection of bonnethead sharks, which has been managed by raising the environmental temperature to >80°F (27°C).

TABLE 2 "NORMAL" REFERENCE RANGES FOR ROUTINE WATER QUALITY ANALYSIS

Parameter	Freshwater	Saltwater
Dissolved oxygen	Saturation ^a	Saturation
Carbon dioxide	<12 mg/L	<12 mg/L
pH	6.5–9.0	7.8–8.3
TAN (total ammonia nitrogen) ^b	0 mg/L	0 mg/L
Toxic un-ionized ammonia (NH ₃) ^b	0 mg/L	0 mg/L
Nitrite	0 mg/L	0 mg/L
Nitrate	<20 mg/L	<70 mg/L
Total alkalinity (carbonate fraction)	>100 mg/L CaCO ₃	>250 mg/L CaCO ₃
Total hardness (Ca and Mg primarily)	>20 mg/L CaCO ₃	>250 mg/L CaCO ₃
<i>If source water is from municipal water supply:</i>		
Total chlorine (free chlorine + chloramines)	0 mg/L	0 mg/L
Free chlorine	0 mg/L	0 mg/L

^a Dissolved oxygen in ponds will fluctuate on a diurnal basis. Concentrations <5 mg/L are dangerous. Mortality will be species-specific and related to time of exposure but may be observed at ≤4 mg/L. Oxygen saturation at room temperature (25°C [77°F]) and sea level will be 8.27 mg/L in freshwater and 6.75 mg/L in seawater (35 ppt or chlorinity of 20 ppt).

^b Under most circumstances, freshwater fish can tolerate total ammonia concentrations <1 mg/L, whereas saltwater fish will usually tolerate TAN <0.5 mg/L. Un-ionized ammonia concentrations <0.05 mg/L are not considered harmful.

See TABLE 3 for an overview of common environmental diseases of fish.

Chlorine, Chloramine, and Other Toxicants:

Aquatic organisms are sensitive to a wide variety of toxicants, particularly **chlorine and chloramine**, which are common additives to city water. Chlorine is also used to disinfect tanks and equipment. Chloramine is a form of chlorine that has been stabilized by amination. When treated for removal of the chlorine molecule, ammonia is released into the system. Both compounds are highly toxic to fish, with adverse effects seen at chlorine concentrations as low as 0.02 mg/L and mortality at 0.04 mg/L. A simple colorimetric test is available to measure chlorine and chloramine in aquatic systems. No chlorine or chloramine should be detected at any time live animals are present. Water samples for chlorine testing should be tested onsite; however, if that is not possible, they may be transported in glass bottles. The chemical can be transient and difficult to detect, so a negative test result may not completely exclude some contamination in the system being evaluated.

To test for chlorine and/or chloramine, kits are available that measure both free and total

chlorine. Free chlorine measures hypochlorous acid (HOCl) and the hypochlorite ion (OCl⁻), which is the active property in bleach. Total chlorine measures free chlorine plus chlorine that is tied up as chloramine. Water treated with chloramines alone will test negative for free chlorine but have high amounts of total chlorine detectable; therefore, testing for both is important. When chloramines are treated with sodium thiosulfate to eliminate the chlorine, ammonia is released into the system. In such an instance, repeated water changes (each of which requires dechlorination, releasing additional ammonia) can result in high ammonia levels that also may be toxic. A properly conditioned biofilter should be able to metabolize the ammonia as it is released, but a new or damaged bacterial bed will not be able to manage the influx of ammonia from repeated deamination of chloramines. This problem can be overcome by using a dechlorinator specifically designed to deal with chloramines by also binding the ammonia byproduct. Effective use of dechlorination products requires testing water for both free and total chlorine before and after use. Following label instructions on products sold from pet stores usually

effectively removes these chemicals; however, in rare instances more chlorine/chloramine than expected may be present in municipal water supplies. Treatment of water supplies will vary, and boluses of chlorine or chloramine may be sent through water lines as part of maintenance protocols in some circumstances. Further, inaccurate calculation of the volume to be treated can also lead to poor performance or failure of dechlorination products.

Chronic exposure to sublethal concentrations of chlorine is a surprisingly frequent problem, even for experienced aquarists. Veterinarians should test water for chlorine (free and total) every time a sample is submitted from a tank that uses a municipal water supply as source water. Clinical indications of sublethal chlorine exposure are nonspecific but may include ragged fins, excess mucus on skin and gills, cloudy corneas, behavioral signs such as lethargy or irritation, and sometimes a history of low chlorine level and chronic mortality.

Other toxicants include hydrogen sulfide and heavy metals. **Hydrogen sulfide** usually is a problem in poorly maintained tanks in which the sediments are not cleaned frequently enough, allowing anoxic areas to develop. Cleaning or other disturbance of these areas can release hydrogen sulfide into the water column, resulting in acute and catastrophic mortality. Another common source of hydrogen sulfide is well water; if this is the case, a distinctive "rotten egg" smell can sometimes be detected. Hydrogen sulfide is volatile and transient, so unless a water sample is collected at the time of the problem, a confirmed diagnosis may not be possible. Acute mortality has been reported at concentrations of 0.5 mg/L, but any detectable hydrogen sulfide should be considered a significant problem.

Heavy metals in water can result in acute, or more often, chronic mortality. If household plumbing includes copper piping, some copper may leach into the water. If released in sufficient volume, this may cause a fish kill. Problems are most likely when water has been allowed to stand in pipes. A copper test of suspect water should confirm the problem. Solutions include running the water before it is placed into the aquarium, or special filtration (eg, activated carbon) to remove metals.

Zinc toxicity has been associated with use of stainless steel vessels to house fish. It has also been reported rarely from public exhibits in which coins were allowed to collect on the substrate or to be ingested by fish.

Dissolved Gases: Of the dissolved gases, oxygen is the most important. In outdoor production ponds, photosynthesis by algae is the primary source of oxygen. A diurnal cycle is established, which coincides with photosynthetic activity. During daylight hours, when photosynthesis occurs, oxygen levels rise and CO₂ levels fall. At night, respiration is the driving force, resulting in a decrease in DO and an increase in CO₂. Most finfish thrive when the DO concentration is >5 mg/L. When DO is <5 mg/L, fish become stressed; depending on species, size, and duration of exposure, a fish kill may result. Cardinal signs of a fish kill caused by hypoxia include sudden, significant mortality, usually noticed early in the morning (when oxygen levels are lowest); often, large fish are affected more than small fish. Fish that are hypoxic often school near the surface of the water and may be seen trying to gulp air, a behavior referred to as "piping." Differential diagnoses for piping includes low DO, high nitrite, and gill disease.

Although low DO is most common early in the morning in outdoor ponds, it can occur at any time. Other common causes of low DO in ponds are cloudy weather, death of an algal bloom, excessive feeding, overstocking, and pond turnover. Unrecognized overstocking can occur in koi ponds if fish spawn successfully and offspring survive and are retained in the system. Pond turnover is a common cause of catastrophic mortality in pond fish. It occurs most frequently in deep ponds (>6 ft) and involves a phenomenon referred to as stratification. Water at the bottom of the pond cools, and a temperature gradient, called a thermocline, develops between warm surface water and cool bottom water. The thermocline acts as a physical barrier between the surface water (epilimnion) and bottom water (hypolimnion). Because photosynthesis, and hence oxygen production, occurs at the surface, the hypolimnion becomes hypoxic and develops a biologic oxygen demand. When the pond is mixed, or "turns over," the oxygen is removed as the biologic oxygen demand of the hypolimnion is satisfied. This sudden removal of oxygen can result in oxygen depletion and a fish kill. The most common cause of pond turnover in the southern USA is a summer thunderstorm, in which energy released from cold rain coupled with wind and wave action is sufficient to mix the pond. Fish kills in Florida have occurred after hurricanes and have been attributed to pond turnover. Pond turnover can also be caused by seining, aeration, or other management

TABLE 3 COMMON ENVIRONMENTAL DISEASES OF FISH

Disease	Problem	Behavioral Signs
Low dissolved oxygen	Hypoxia	Piping at surface; large fish affected more than small ones
Gas bubble disease	Supersaturation (often N ₂ gas)	Lethargy, buoyancy problems
Carbon dioxide toxicity	CO ₂ >40 mg/L	Lethargy at surface
Ammonia toxicity (new tank syndrome)	Un-ionized ammonia >1 mg/L pH >8	Lethargy, anorexia, spinning, convulsive swimming
Nitrite ^a toxicity	NO ₂ >0.1 mg/L ^a Low chloride (freshwater)	Piping at surface
Nitrate ^b toxicity	NO ₃ -N ≥70 mg/L Low (no) iodine, O ₃	Lethargy
Old tank syndrome	Total alkalinity (TA) ~0 mg/L pH <6, high total ammonia nitrogen (TAN)	Lethargy, poor appetite
Lack of minerals	Total hardness <20 mg/L Use of distilled water	Sudden death
Chlorine toxicity	Detectable chlorine	Acute: sudden death Chronic: lethargy, irritation
Hydrogen sulfide toxicity	Detectable H ₂ S (rotten egg smell)	Acute: sudden death Chronic: lethargy, poor appetite/growth
Copper toxicity	Cu ²⁺ >0.2 mg/L Low alkalinity	Sudden death
Zinc toxicity	Coins in exhibit Stainless steel, acidic pH	Lethargy, anorexia
Stray voltage	Electrical short, mechanical problem	Irritation, mortality

^a There is tremendous species-specific variation to nitrite toxicity. Environmental conditions, especially chloride concentration, can mitigate the effects. Most test kits measure mg/L N●₂ N. To convert to N●₂ (mg/L) concentration, this value must be multiplied by 3.3.

^b Most test kits measure mg/L N●₃-N. To convert to N●₃ (mg/L) concentration, this value must be multiplied by 4.4.

practices that result in mixing of the epilimnion and hypolimnion. Fish kills caused by pond turnover can be avoided by performing a weekly oxygen profile during periods of greatest risk (usually during hot, summer weather). If stratification is detected, the pond should be aerated or mixed to break down stratified layers before a significant oxygen demand layer can develop. Turnover events resulting in localized areas of low DO are common causes of wild fish kills during the summer in

lakes, ponds, and even rivers in the southern USA. Although rare, stratification related phenomenon can occur in aquariums and other aquatic systems. Under some conditions, flow rate, current patterns (related to tank design), and oxygen demand can cause layering (ie, stratification) and consequent focal areas of anoxia.

When assessing DO and aeration in indoor systems or exhibits in which the primary source of DO is an aeration device, and water is clear, the percent saturation

TABLE 3 COMMON ENVIRONMENTAL DISEASES OF FISH (*continued*)

Physical Signs	Mortality	
	Acute	Chronic
Flared gills, dark	Catastrophic mortality	Ongoing
Gas bubbles in gill capillaries, fins, and eyes; exophthalmos ("popeye")	Catastrophic mortality	Ongoing
None	Yes	Yes
Darkened	Catastrophic mortality	Ongoing
Gills and blood dark brown color	Yes	Yes
Swelling around throat ("goiter")	No	Yes
None	No	Yes
None	No	Yes
Acute: none Chronic: excess mucus, cloudy eyes, gill inflammation/necrosis	Catastrophic mortality	Ongoing
None	Catastrophic mortality	Ongoing
None	Catastrophic mortality	Ongoing
None Enlarged abdomen (coins in GI tract)	Not usually	Yes
Broken back	Yes	Yes

should be considered along with the total DO reading. The amount of oxygen that water can hold in saturation varies with water temperature, salinity, and altitude. Of these three factors, water temperature is the most important. As any of these variables increase, the amount of oxygen in solution at saturation decreases. Saturation tables are available to determine percent saturation for a given DO if temperature, salinity, and altitude are known. Many modestly priced oxygen meters now provide data on the concentration of DO (mg/L) as well as the percent saturation. If oxygen saturation is <100%, it may indicate inadequate aeration for the bioload or sanitation problems (development of

anoxic, organic-rich areas within the system). In either case, an inability to maintain a system at, or very near, 100% oxygen saturation requires correction. Most fish do well if DO is >5 mg/L; however, the percent saturation should be considered an indicator of the system's health.

Gas bubble disease is caused by supersaturation of water with dissolved gases. Although oxygen and/or CO_2 can contribute to supersaturation, the predominant gas contributing to the problem is usually nitrogen. Gas bubble disease can result in acute catastrophic or chronic mortality. It may occur transiently and can be difficult to confirm. Supersaturation should be considered when unexplained

mortality is encountered in an aquarium setting. One common source of supersaturation is the use of well water that contains high concentrations of nitrogen (gas) or CO_2 . This problem is easily remedied by aerating the water before it comes into contact with the fish. Common causes of gas bubble disease in public aquaria include the use of cavitating pumps, leaks in plumbing on the intake side (allow for gas to enter and be forced under pressure through the pump), and sometimes excessive turbulence in cold water exhibits. In these cases, the supersaturation is caused by atmospheric nitrogen gas. Gas bubble disease is manifest by exophthalmos and the presence of tiny gas emboli within fins, corneas, or other tissue. The presence of gas emboli within gill capillaries is diagnostic. Treatment of gas bubble disease is vigorous aeration to volatilize excess gas and correction of underlying mechanical problems. Confirming a case of supersaturation can be extremely difficult, especially if mortality was acute and gas emboli cannot be detected in tissue. Sometimes, tiny gas bubbles may be visible on the inside of the glass in an aquarium, suggesting a lot of gas is in the water column. A satumeter will measure all dissolved gases and is the best tool for direct detection of the condition. If DO of the system is known, this equipment can be used to calculate the concentration of nitrogen gas present. Permanent correction of the problem includes identification and correction of the source of the excess gas.

CO_2 can be toxic to fish at concentrations $>12 \text{ mg/L}$. The concentration of CO_2 in solution in ground water is typically $<10 \text{ mg/L}$. Water from affected systems often is acidic ($\text{pH} < 7$). A quick field test for excessive CO_2 involves vigorous aeration of a bucket of suspect water for 1 hr. A significant increase in pH (ie, >1 unit) over the hour is indicative of excess CO_2 . Fish exposed to high concentrations of CO_2 may be quite lethargic and even disoriented. Hybrid striped bass exposed to toxic levels of CO_2 ($\sim 40 \text{ mg/L}$) at the surface have been observed with their backs out of the water. These fish reacted dramatically to salt added to the affected tank by trying to jump out of the water. When CO_2 is high in the water column, fish are not able to release it from the bloodstream, resulting in hypercarbia and acidemia. The condition is exacerbated by low concentrations of DO. Nephrocalcinosis and visceral granuloma were reported in salmonids exposed to a high level of CO_2 in the water, leading to metabolic acidosis and urinary and tissue precipitation of calcium, around which

extensive granulomas developed. Treatment for CO_2 toxicity is increased and vigorous aeration. Stocking density should be assessed and may need to be decreased.

Nitrogenous Compounds: Nitrogenous wastes enter the aquatic system directly from excretion by fish, decomposition of organisms in the water, or degradation of fish food. Fish foods are generally very high in protein, often $>38\%$, and can add significant quantities of nitrogen to a system. Nitrogen is eliminated from fish by passive diffusion of ammonia (NH_3) from gill capillaries. Once NH_3 is released into the water, it enters the nitrogen cycle, a natural process in which bacterial populations change ammonia to nitrite (NO_2) and then to nitrate (NO_3). Nitrate is most commonly removed from aquariums by water changes. In large, commercial systems, discharge of salt water to municipal water supplies is not allowed, and nitrate accumulates. It can be removed by anaerobic filtration, which converts NO_3 to nitrogen gas (N_2), which is volatile and quickly leaves the system. These anaerobic filters are expensive and can be challenging from the design perspective, so they are not common except in very large exhibits. Plants or algae, if present in a system, will use nitrogen products directly. Toxicity of each of these parameters is discussed below.

NH_3 is highly toxic and frequently limits fish production in intensive systems. It is also dynamic, and when it enters the aquatic system, an equilibrium is established between NH_3 and ammonium (NH_4^+). Of the two, NH_3 is far more toxic to fish, and its formation is favored by high pH (>7) and water temperature. When pH exceeds ~ 8.5 , any NH_3 present can be dangerous. In general, a normally functioning aquatic system should contain no measurable NH_3 because as soon as it enters the system, it should be removed by aerobic bacteria in the environment. Ammonia test kits do not typically measure NH_3 directly but instead measure the combination of NH_3 and NH_4^+ , referred to as total ammonia nitrogen (TAN). A TAN $< 1 \text{ mg/L}$ is usually not cause for concern unless the pH is >8.5 . However, if the amount of NH_3 is increased, an explanation should be sought. The amount of toxic NH_3 present can be calculated using the TAN, pH, and water temperature. When NH_3 levels exceed 0.05 mg/L , damage to gills becomes apparent; levels of 2 mg/L are lethal for many fish. Fish exposed to ammonia may be lethargic and have poor appetites. Acute toxicity may be suggested by neurologic signs such as spinning, disorientation, and convulsions.

Overfeeding or malfunction (death) of a biologic filter are common causes of increased NH_3 . If possible, a water change (250%) should be done as soon as high NH_3 levels are detected. When changing water to alleviate NH_3 toxicity, it is imperative to consider whether source water contains chloramines, because this can contribute to increased NH_3 concentrations. If TAN is extremely high (ie, >5 mg/L) and pH is acidic (ie, <6), fish should be moved to a clean system (tempered for pH and temperature) to avoid a sudden shift from NH_4^+ to NH_3 as the pH rises during the water change. Feeding should be discontinued or significantly reduced until the problem has been corrected.

Two conditions encountered in pet fish medicine are characterized by high NH_3 concentrations, appropriately called new tank syndrome and old tank syndrome.

New tank syndrome occurs when NH_3 levels rise during the first 2–3 wk after a new system is set up, because the biofilter has not had time to develop. In this situation, the NH_3 concentration will be increased, but all other parameters should be within normal limits. Beginning aquarists are likely to overstock and overfeed new systems, resulting in significant NH_3 spikes and, subsequently, sick or dying fish. Daily monitoring of TAN coupled with frequent water changes to manage NH_3 will be necessary until the biofilter cycles. Maturation of the biofilter will be indicated by decreasing concentrations of TAN and increasing concentrations of NO_2^- (which will decrease as the filter conditioning process is completed). Damage to a biofilter can be caused by use of antibiotics or other chemicals and result in a similar situation. It usually takes ~6 wk for a new biofilter to cycle. When this time frame is extended, there may be complications attributed to poor design, use of chemicals, or lack of adequate oxygen and carbonate (alkalinity) in the filter bed. To prevent new tank syndrome, aquarists use several “tricks” to get biofilters started. These include purchasing commercially available nitrifying bacteria from a reputable source, “feeding” the bacteria with fish food or ammonium chloride before adding fish, or adding fish slowly to the new system.

Old tank syndrome is less frequently recognized. It is characterized by extremely high NH_3 levels (TAN may be >20 mg/L), extremely low pH (usually <6 , may be <5 in severe cases), and a complete absence of alkalinity. The condition is caused by complete exhaustion of buffering capacity within a system, usually precipitated by

improper management over a period of months. Over time, the biofilter bacteria acidify the water through the nitrification process. As the buffering capacity (alkalinity) is exhausted, organic acids that have accumulated drop the pH, and the acidic environment kills the biofilter, leading to an accumulation of NH_3 . When correcting such a situation, it is important to eliminate as much “bad” water as possible and avoid a shift in residual $\text{NH}_3\text{-H}^+$ to the toxic un-ionized state (NH_3) as pH rises. A simple water change under such circumstances can result in catastrophic mortality as pH rises above 7 and ammonium shifts to un-ionized (toxic) ammonia. Over-the-counter products that chemically remove or bind NH_3 can help prevent mortality, but the system must be thoroughly cleaned and restarted. It will take several weeks for the system to recover.

The second breakdown product in the nitrogen cycle is nitrite (NO_2^-), which is also toxic to fish. Most test kits actually measure nitrite-nitrogen rather than nitrite. A conversion factor of 3.3 can be used to calculate the actual nitrite concentration ($3.3 \times \text{mg/L NO}_2\text{-N} = \text{mg/L NO}_2^-$). NO_2^- can enter the bloodstream passively across the gill epithelium. It complexes with hemoglobin to form methemoglobin, resulting in methemoglobinemia, or **brown blood disease**. As in other species, RBCs containing methemoglobin are unable to transport oxygen, resulting in a physiologic hypoxia regardless of oxygen content in the water. There are species-specific differences in fishes' susceptibility to NO_2^- toxicity (eg, centrarchids [bass, bluegill, etc] are refractory). Marine fish were thought to be protected from NO_2^- toxicity by salts in their environment; however, red drum have developed brown blood disease in the presence of NO_2^- . A tentative diagnosis of brown blood disease can be made by observing the characteristic chocolate brown color of the gills, although this change is not detectable until methemoglobin levels are substantial. In severe cases, the color of blood samples will also be abnormally dark. Methemoglobin concentrations in the blood can be determined, although this is not necessary for clinical management. A water quality test can confirm the presence of NO_2^- . Fish affected with methemoglobinemia typically show signs of hypoxia, often manifest by piping.

The most rapid treatment for NO_2^- toxicity is a water change, but this is not feasible in large ponds. Increasing chloride (Cl^-) concentration in the water creates a

competitive inhibition at the gill epithelium between Cl and NO₂. Many ornamental ponds and aquaria are maintained with residual chloride levels because of the addition of salt (1–3 ppt) as a relatively permanent treatment. In these cases, nitrite is less likely to be a problem, because chloride levels are increased by the residual salt concentration. In freshwater production ponds for channel catfish, a ratio of 6 parts Cl to 1 part NO₂ has effectively prevented or treated methemoglobinemia caused by nitrite exposure. The absorption of Cl⁻ across the gill membrane reduces the amount of NO₂⁻ entering the bloodstream; consequently, the percentage of hemoglobin converted to methemoglobin is decreased, resulting in immediate relief to the fish and a cessation of mortality usually within 24 hr. To determine the amount of salt required to increase chloride levels in large ponds, the concentrations of NO₂ and Cl present must be measured by commercial test kits. The concentration of Cl needed (mg/L) = (6 × NO₂) - Cl present. Once the necessary concentration of Cl⁻ to be added is known, the volume of water can be calculated in acre-feet or gallons (1 acre foot = 1 surface acre, 1 foot deep or 325,850 gal.), and salt can be added to achieve the desired Cl level (4.5 lb of salt will add Cl at 1 mg/L to 1 acre-foot of water, or 1 lb of salt will add 1 mg/L Cl to 72,411 gal.). In aquariums and garden ponds, a water change and filter maintenance are recommended to correct nitrite problems; however, salt may still be used to halt mortality during a sudden increase in NO₂ exposure for many freshwater fish.

Although considered less toxic than ammonia or nitrite, chronic exposure to nitrate (NO₃-N) has been associated with development of goiter in some species of elasmobranchs. As mentioned earlier for the nitrite test kit, most test kits for nitrate actually measure NO₃-N. To convert to the actual NO₃ concentration, this number must be multiplied by a correction factor of 4.4. Practitioners should read the literature carefully to distinguish reports of NO₃-N versus NO₃ concentrations. Chronic exposure to NO₃-N concentrations of 70 mg/L resulted in histologic evidence of goiter in white spotted bamboo sharks within 29 days of exposure. Chronic exposure to NO₃-N of 35 ± 5.12 mg/L resulted in development of overt goiter and 100% mortality of brown spotted bamboo sharks and 18% mortality of white spotted bamboo sharks in a recirculating system after ozone was added. Goiter is a complex disease, and there seem to be species-specific differences in susceptibility that are not well understood. Contributing

factors include inadequate dietary iodine or environmental iodide, ozonation, and nitrate exposure. Goiter is characterized by a ventral midline swelling in the cervical region of elasmobranchs. Diagnosis can be confirmed by measuring T₄. In healthy (no clinical or histologic evidence of goiter), captive, white spotted bamboo sharks housed in a natural seawater system, T₄ was 14.77 ng/mL (range of 9.57–30.50 ng/mL in five animals). Lower levels have been reported in sharks with visual evidence of goiter. If an animal is necropsied, thyroid tissue can be evaluated histologically to confirm the diagnosis. Nitrate is well recognized as a goitrogenic compound and may be present in fairly high concentrations (>70 mg/L NO₃-N) in recirculating aquarium and aquaculture systems. Nitrate blocks the uptake of iodine by the thyroid gland, resulting in an inability to produce thyroid hormone and constant stimulation of the glandular tissue. Fish and elasmobranchs absorb micronutrients, including iodine, from the water column. In an ozonated system, the problem is exacerbated because iodine is converted to iodate (IO₃), which is not biologically available. Dietary supplementation of iodine at 10–30 mg/kg/wk is recommended for elasmobranchs to prevent development of goiter. Environmental iodine should be maintained with concentrations of 0.15 µM (0.01–0.02 mg/L) iodide (I⁻). Potassium iodide (Lugol's solution) has been used to increase environmental iodide concentrations in public aquaria. Goiter occurs in teleosts and other aquatic species but is not as easily recognized. The body shape of many elasmobranchs allows for easy recognition of the problem during a visual examination.

pH and Carbonate Compounds: The carbonate cycle is an important concept in water quality management, and its complexity is reflected in the dynamic interactions between CO₂, pH, total alkalinity, and total hardness. In aquatic systems containing algae or plants, CO₂ fluctuates on a diurnal basis, similar but opposite to fluctuations in DO. As CO₂ concentration changes, the pH of the water also changes. As CO₂ concentration decreases during daylight hours, pH rises, peaking in late afternoon. Conversely, as CO₂ concentration increases during the night, pH falls, reaching its lowest level just before daylight. A diurnal pH change from 6.5 to 9 is not unusual in a freshwater fish pond with a healthy algal bloom. Most freshwater fish can tolerate reasonable fluctuations in pH, and the lethal limits for many species are approximately 4 and 10. Marine fish are much less tolerant of pH

fluctuations the marine environment is much more stable, with a pH of 8.2–8.3. For marine tanks, a pH in the range of 7.8–8.5 is usually considered normal.

Although fish kills caused by improper pH are rare, hydrated lime ($\text{Ca}(\text{OH})_2$) is sometimes added to freshwater ponds by mistake. $\text{Ca}(\text{OH})_2$ will rapidly increase the pH to >10, killing all fish present. Correct liming of ponds is mentioned briefly below.

CO_2 released into an aquatic system enters the carbonate cycle: $\text{H}_2\text{O} + \text{CO}_2 \leftrightarrow \text{H}_2\text{CO}_3 \leftrightarrow \text{H}^+ + \text{HCO}_3^- \leftrightarrow 2\text{H}^+ + \text{CO}_3^{2-}$. The process is driven by the presence of carbonate (CO_3^{2-}) in the system, which is measured by testing the total alkalinity (TA). For most fish, water should be of moderate alkalinity, 100–250 mg/L. When TA is <50 mg/L, water is considered low in alkalinity, and buffering ability will not be adequate to prevent major pH fluctuations. Toxicity of copper sulfate, an algicide and effective parasiticide, is closely associated with TA, and the compound cannot be used safely if TA is <50 mg/L. To raise alkalinity, dolomite (CaCO_3 and MgCO_3) or agricultural limestone (CaCO_3) may be added to the system. Dolomite is most convenient for small systems and can be purchased in 50-lb bags and used to effect. Baking soda (NaHCO_3) can also be used to increase alkalinity in small systems. To raise alkalinity in outdoor ponds, agricultural limestone is commonly used; the method is similar to “liming” a pasture. Soil samples can be tested to determine how much lime needs to be added, but in general 1–2 tons per surface acre works well. The limestone should be unloaded on the bank of the pond and then usually has to be moved into the water using a shovel and boat. It does not need to be distributed throughout the entire surface area of the pond, but it takes several weeks to get into solution. Consequently, the alkalinity will change slowly, so it should be monitored for several days, or weeks if necessary, after the addition of these compounds. Lack of alkalinity can impair biologic filtration, resulting in accumulation of ammonia in a system. Alkalinity should be ≥ 100 mg/L in freshwater systems and ≥ 250 mg/L in saltwater systems.

Total hardness (TH) should not be confused with TA. Both TH and TA are reported as mg/L of CaCO_3 . The difference is that the test for TA measures the HCO_3^- , OH^- , and CO_3^{2-} fraction, and the test for TH measures the calcium (Ca^{2+}) fraction. The test for TH also measures other divalent cations in the system, including magnesium, manganese, iron, and zinc. TH is important in determining the amount of calcium available to young fish. Calcium chloride,

dolomite, or agricultural limestone can be added to water to increase calcium concentration. For channel catfish, TH >20 mg/L is required for normal skeletal growth and development. Fish absorb minerals from the water column; therefore, use of water with very low TH, which can be caused by use of deionized water, can result in poor growth and mortality.

Salinity: The salinity of seawater is determined by a complex array of salts. Seawater is ~3% salt, which is 30 ppt (30 g/L). For marine fish, many of the micronutrients present in seawater are essential, so it is necessary to buy or make “sea salts.” In freshwater, salinity may be increased using table or water softener salt (NaCl). Salt is often used in freshwater systems to reduce osmoregulatory stress or to eliminate certain ectoparasites. Salinity can be measured with a clinical refractometer or with a hydrometer purchased from a pet store. It is important not to confuse the chloride (Cl^-) test, which is used in assessment of NO_2Cl in freshwater systems with high nitrite, with salinity. The chloride test measures ppm chloride; if any salinity at all is present in the water (ie, salt has been added), the test will not work properly because the amount of chloride present is so high. The easiest way to calculate the amount of salt needed to increase salinity is to calculate the total volume in liters (3.8 L = 1 gal.), remembering that 1 g/L = 1 ppt. Most non-pond freshwater systems can be maintained with a residual salinity of 1–3 ppt, whereas most saltwater systems will have a salinity of 30–33 ppt. Some freshwater species (eg, wild-caught Amazonian fish) may not tolerate permanent exposure to the low levels of salt mentioned above.

Temperature: Environmental temperature is extremely important to the health and well-being of fish and other aquatic species. As poikilotherms, fish have a very limited ability to control body temperature, and physiologic systems are designed to work optimally at species-specific temperature ranges. Sudden changes in temperature, of even just a few degrees, can result in compromise of immunity and increased pathogenicity of some infectious agents. Some fish (eg, channel catfish or koi) are very tolerant of a wide range of environmental temperatures; however, this does not imply that drastic temperature fluctuations are acceptable even for these species. Others, such as discus, thrive in only a very narrow temperature window. When evaluating housing and husbandry,

practitioners should know the temperature at which animals are being housed and confirm that it is appropriate for the species. Suboptimal environmental temperature is an important component in some fungal infections. Many infectious agents, especially viruses, have specific temperature windows at which they cause clinical disease and mortality. Fish infected but maintained at temperatures above or below these optimal ranges are more likely to survive infection but may become carriers. When handling or transporting fish, moderating temperature change is essential. A general rule is 1°F, or even 1°C, per hour as a maximum change. Some fish may tolerate more or less of a change over time.

ENVIRONMENTAL CONSIDERATIONS FOR SELECTED INFECTIOUS DISEASES

A number of infectious diseases have specific environmental parameters that can substantially enhance the impact of an outbreak or make an outbreak more difficult to control. A few of the more significant examples are mentioned below.

Mycobacteria: *Mycobacterium* spp is an important infectious pathogen of fish and other aquatic organisms. There have been many species of *Mycobacterium* identified in fish; however, all are nontuberculous and most are environmental. Typically, environmental conditions common in aquaculture favor growth of *Mycobacterium*. These conditions include low DO concentrations, accumulation of organic debris and particularly biofilms, as well as acidic pH. *Mycobacteria* are hydrophobic because of their thick, waxy cell walls and tend to adhere to surfaces and each other. Once infected fish are present in a system, these animals may continually shed the organism in feces and cells released from external lesions. Ultraviolet light (ie, UV filtration) may decrease the number of these bacteria in the water column, which may help decrease transmission; correction of these environmental factors can also enhance control efforts. In aquaculture, infected fish are almost always culled. In display aquaria, however, the decision may be made to maintain infected fish. In these cases, environmental management can be an important part of the protocol developed for the care of affected animals. Maintaining oxygen concentration near saturation and avoiding acidic and organically rich environments in the presence of some type of disinfection on the system (eg, UV or ozone) can greatly enhance

the quality of an exhibit populated with mycobacteria-positive fish. In this situation, the exhibit should be clearly labeled as mycobacteria-positive, and employees should be properly trained to minimize risk of disease transmission from the contaminated exhibit to personnel working in the area or to other systems or animals.

Bacterial Gill Disease: Bacterial gill disease is an important disease of cultured salmonids and has been reported in other species, including hybrid striped bass. It is rare in aquarium fish. It is caused by bacteria in the genus *Flavobacterium* and other closely related genera and is manifest by gill pathology (hyperplasia, clubbing of gill filaments) and subsequent mortality. However, bacterial gill disease has an important environmental component, and mechanical damage to gill epithelium, which may be caused by excessive crowding and debris in the water column, is believed to be an important predisposing factor. Cleaning the environment, removing debris, and decreasing stocking density all contribute to a positive treatment outcome. Correcting these underlying problems also prevents recurrence of the condition. Potassium permanganate can be useful in removing organic detritus from an affected freshwater system. However, caution is advised, because this treatment may cause mortality in fish already compromised with significant gill damage.

The Role of Temperature in Infectious Diseases: Many infectious diseases of fish occur in a specific "temperature window," and adjusting temperature may be an important part of successful treatment. For example, *Fusarium solani* is a fungus that has been linked to suboptimal environmental temperatures in bonnethead sharks. Infected sharks must have environmental temperatures raised above 80°F (27°C) to control or prevent the infection. *Saprolegnia*, a common fungus-like oomycete of freshwater and brackish water fish, is also often associated with suboptimal environmental temperature. Raising water temperature a few degrees may significantly improve response to treatment. Clinicians are encouraged to determine optimal environmental temperature when fish are observed with this condition and to make appropriate corrections if needed.

Temperature is also critical in control of most viral diseases of fish. Two important diseases of koi, spring viremia of carp (SVC) and koi herpes virus (KHV), have strong temperature predilections. This should

always be kept in mind when working with these popular pets. It should be remembered that KHV is a warm water disease. Infected koi typically develop disease when water temperatures are in the range of 64°–81°F (18°–27°C). Fish with KHV typically exhibit significant gill lesions and signs of hypoxia. In contrast, SVC is a cool water disease, typically occurring at water temperatures of 41°–64°F (5°–18°C). Both of these diseases are reportable at the state and federal levels. Although KHV is considered endemic in the USA, SVC is a foreign animal disease, and the USDA will impose quarantine and forced destruction of fish if an infection is confirmed. Consideration of water temperature is an important first step when confronted with a disease in this species.

Almost all viral diseases of fish have specific temperature ranges at which they cause active disease. Clinicians must familiarize themselves with diseases of concern and the temperatures at which they occur in the species at hand.

Excessive Organic Load: Organic debris can accumulate because of poor husbandry or poor system design. Detection of accumulated detritus can be surprisingly difficult when areas of “dead space” exist in a system, because these areas are often not directly visible. Environmental parameters that suggest this problem include an inability to maintain DO concentrations at or near saturation. Further, total alkalinity and pH may be lower than that in source water. All of these changes suggest a substantial amount of decomposition of organic matter is occurring somewhere in the system. Pet owners or aquarists may need to break the system down to locate and remove the accumulated material.

In these systems, a presenting disease problem may be infestation of external surfaces of the fish with *Trichodina*, a common ciliate. *Trichodina* is often considered a bio-indicator of suboptimal conditions that may include overcrowding, overfeeding, and excessive organic debris (ie, a dirty system). Thoroughly cleaning the system, removing detritus, and correcting design flaws when possible are important to correct these problems. Treating the parasite without correcting system problems will result in continual recurrence and frustration. Other infectious agents that may be observed in the presence of poor sanitation include sessile ciliates such as *Epistylis*, *Heteropolaria*, *Ambiphyra*, and *Apiosoma*. Saprophytic fungi and fungi-like diseases (eg, the oomycete *Saprolegnia*) may also be seen when hygiene is a concern.

Infectious Sequelae of Environmental Disease: Fish that survive a severe environmental insult, such as an acute hypoxic event, are at increased risk of opportunistic bacterial infections. Common infections that may occur 1–2 wk after an insult could include infections with *Aeromonas hydrophila* and *Pseudomonas fluorescens* in freshwater systems, and *Vibrio* spp in marine systems. Given this possibility, it may be prudent to treat valuable fish with a broad-spectrum antibiotic with general efficacy against gram-negative organisms after survival of a significant insult. In many cases, good water and a quiet environment will be sufficient for recovery, but when in doubt, the use of antibiotics may be justified, especially if they can be provided in feed. Once fish start to break with an infection, they often go off-feed, making treatment much more difficult.

AQUARIUM FISHES

Aquatic medicine has emerged as a recognized specialty within the practice of zoologic medicine. Fish medicine, an important component of the aquatic specialty, is evolving, with distinct subspecialties of aquaculture and production medicine (see AQUACULTURE, p 1743) as well as pet and exhibit fish medicine that focuses on individual animals. This chapter focuses on pet and exhibit fish medicine.

The business of ornamental fishes, which includes specimens that may be added to

zoologic collections, can be broadly divided into freshwater and marine species. Most pet fishes are freshwater, and many are farm raised in the USA, Asia, or elsewhere. Many fish sold through the pet trade are imported to the USA. Except for a small number of species such as some clownfishes (*Amphiprion* spp), dotybacks (*Pseudochromis* spp), gobies (primarily *Elacatinus* spp), blennies (primarily *Meiacanthus* spp), and seahorses (*Hippocampus* spp), most marine fishes are wild caught.

The trade in ornamental fishes is a global industry, and fishes are often moved through several dealers before reaching a wholesale or retail outlet. The source of these fishes is an important consideration when designing quarantine protocols and anticipating the types and severity of disease that may be seen in recently acquired animals. Some fish species, whether marine or freshwater, are particularly prone to parasitic and bacterial infection during the quarantine period (first 30 days), including the first few weeks after arrival in a pet store or home aquarium.

Cyprinids such as koi and fancy goldfish for ornamental ponds are popular pets and typically respond well to veterinary care. Many of the highest quality are imported from Japan (koi) or China (fancy goldfish) and may have significant value (up to several thousand dollars for show-quality koi). Many are large enough for clinical manipulation, are quite hardy, and often have significant emotional value to their owners. These fish are susceptible to several diseases of regulatory concern, most notably spring viremia of carp and koi herpesvirus, which are both reportable diseases.

Clinical management of individual pet fish, exhibit animals, and valuable broodstock has changed dramatically in recent years. Advances include use of nonlethal methods to diagnose disease and more sophisticated treatment options. Radiology and ultrasound are particularly well suited for use in aquatic species, as are CT and MRI. They are especially valuable for evaluation of the gas bladder, investigation of internal masses, and more. Development of blood culture techniques to accurately identify bacterial agents and perform susceptibility tests before starting antibiotic therapy has been useful to decrease the need to euthanize, or surgically biopsy, an animal to achieve an accurate diagnosis. Surgical advances, including use of exploratory laparotomy and gas bladder repairs, have salvaged animals that previously would have been euthanized.

The equipment needed to treat fish in a veterinary practice is modest. In addition to equipment already on hand (eg, microscope, glass slides and cover slips, basic surgical or dissecting tools), water quality parameter testing equipment is needed (*see AQUATIC SYSTEMS*, p 1766).

TABLE 4

COMMON PARASITIC DISEASES OF SELECTED FISH FAMILIES

Parasite	Cyprinidae	Characidae
Ciliates		
“Ich”	✓	✓
<i>Chilodonella</i>		
<i>Tetrahymena</i>		
“Flagellates”		
<i>Ichthyobodo</i>	✓	
<i>Piscinoodinium</i>	✓	
<i>Spironucleus</i>		
<i>Cryptobia</i>		
Coccidia	✓	
Myxozoans		✓
Cestodes	✓	
Monogeneans	✓	✓
Gyrodactylids	✓	✓
Ancyrocephalids		✓
Dactylogyrids	✓	
Nematodes		✓

Note: A table cell that is not marked does not mean the parasite is not seen in that family.

In addition to these basic tools, a practice should have a few fish tanks for use as hospital systems. These can be 10- or 20-gal. tanks with simple foam filters and aeration pumps. A dechlorinator such as sodium thiosulfate should be on hand if the practice uses water that contains chlorine or chloramine. In addition, tricaine methanesulfonate (MS-222) and baking soda should be available for sedation or anesthesia.

Other useful equipment includes a 1-L plastic graduated cylinder for measurement of water volume, a balance to weigh out anesthetic, and a battery-powered aeration pump if an anesthetized fish is to be moved around the clinic for radiology, surgery, or other procedures. For surgery, a 10- to 20-gal. tank works well as a receptacle. An egg crate lighting panel, or a plexiglass or plastic cover with small holes drilled in it, can be placed over the tank to allow water to flow over the fish and back to the tank. The fish can be positioned in a v-shaped foam "bed," and a small, submersible aquarium pump and flexible tubing can be used to circulate anesthetic-treated, aerated water out of the tank and over the gills. Use of equipment that can be sterilized after each patient is advantageous.

Veterinarians who offer fish medicine should be aware of evolving regulatory concerns, including the current USDA accreditation programs. In addition, aquarium fishes are susceptible to several reportable diseases, which include spring viremia of carp (see p 1813), koi herpesvirus (see p 1812), epizootic ulcerative syndrome (see p 1803), and red sea bream iridovirus (see p 1814).

FISH FAMILIES

This brief introduction to fish families is intended to provide veterinarians new to fish medicine with information on anatomy and pathogens common to those families. Fishes can be first split into two major groups: the cartilaginous fishes such as sharks and stingrays, and the bony fishes. To further divide them, bony fishes commonly kept as pets or display animals usually belong to one of the two subcohorts of Ostariophysi or Neoteleostei.

For an overview of common parasitic and viral diseases of aquarium fish, see TABLES 4 and 5. Susceptibility of specific families of fish to specific pathogens is implied; however, the absence of mention of a

Virus	Cyprinidae	Characidae
Rhabdovirus		
Spring viremia of carp	Koi, goldfish	
Herpesviruses		
Carp pox	Koi	
Koi herpesvirus	Koi	
Herpesviral hematopoietic necrosis	Goldfish	
Iridoviruses		
<i>Megalocytivirus</i>		
<i>Lymphocystivirus</i>		

Note: A table cell that is not marked does not mean the virus is not seen in that family.

specific pathogen does not mean that other families of fish are refractory.

Ostariophysi

Fishes that belong to this subcohort are considered to be basal fishes; this does not mean they are primitive. They have a unique chemical alarm system associated with their skin. If the epithelium is damaged, a material called schreckstoff is released by specialized club cells in the epidermis. It induces a flight response when detected by nearby related fishes. These fish also have cellular bone, which lends itself well to fracture stabilization techniques.

Ostariophysi are physostomous, which means they have a pneumatic duct that connects the anterior lobe of the gas bladder to the dorsum of the esophagus.

Another unique feature of ostariophysi is the presence of a Weberian apparatus, which amplifies sound. This apparatus consists primarily of a small series of auditory bones connected to the gas bladder.

Ostariophysi includes popular aquarium fishes that belong to the families Cyprinidae and Loricaridae and the order Characiformes.

Cyprinidae: The family Cyprinidae contains more fish species than any other family of freshwater fishes, and many are popular as pet fishes. Cyprinids have a widespread distribution, including Asia and North America. Representative cyprinids include goldfish, koi, barbs, danios, most of the freshwater sharks (eg, redbtail, rainbow, and bala), and rasboras.

The primary distinguishing anatomic features of this family are the lack of a stomach and a dual-lobed gas bladder. They also often have a diffuse hepatopancreas, and the posterior kidney is usually positioned between the two lobes of the gas bladder. The absence of a stomach means attention must be given to feeding practices, and the bioavailability of some oral drugs may be lower. Cyprinids benefit from several feedings per day. Related to feeding, buoyancy control is a common problem in fancy goldfish such as orandas, ryukins, etc, due to aerophagia. This can be avoided by feeding sinking feeds.

Mycobacterial disease is a frequent problem in zebrafish (danio) research colonies but can also be seen in other cyprinids. Columnaris disease, caused by *Flavobacterium columnare*, is frequently a source of high mortality in koi and zebrafish. *Edwardsiella ictaluri* is also a problem in zebrafish.

Microsporidia (*Pseudoloma*) is a fungal parasite of concern in zebrafish.

Characiformes: The primary representatives of this order are the tetras, such as neon, cardinal, etc. Unlike the cyprinids, characins have a stomach and pyloric caeca. They usually have a single-chambered gas bladder. Although they are similar to the smaller cyprinids externally, most members of Characiformes have a small adipose fin.

Mycobacteriosis and columnaris are common bacterial diseases of characins.

Microsporidia (*Pleistophora*) is a fungal parasite of concern in tetras.

TABLE 5 COMMON VIRAL DISEASES OF SELECTED FISH FAMILIES (*continued*)

Loricariidae	Cichlidae	Poeciliidae	Osphronemidae
	✓		
	✓	✓	✓
	✓		

Loricariidae: Originating from South America, this family contains the popular armored catfishes, the plecos (short for plecostomus) and the small *Motocinctus* commonly kept in planted tanks. Their scales are modified into plate-like scutes. They usually have a ventrally located mouth. Most are omnivorous, with some being herbivorous. Although some plecos such as the genus *Panaque* are said to be obligate wood-eaters in the hobby literature, some sources indicate this is not true. Accordingly, these fishes have a long intestine. Many of the plecos are able to obtain oxygen through their stomach after swallowing air at the water surface.

Callichthyidae: Another group of popular armored catfishes, including the genus *Corydoras*, belongs to this family. Like the loricariids, the scales of these fishes are modified into armor-like scutes. They have small barbels on either side of the mouth. Axillary glands are located beneath the skin of the shoulder and are the source of the venom that causes punctures by their pectoral fins to be painful. These fishes often scurry to the water surface to ingest air; oxygen is then absorbed via the intestine.

Corydoras spp appear to be very susceptible to infection with *F columnare*.

Neoteleostei

This subcohort of fish families contains the more advanced fishes. Unlike the ostariophysians, the members of this superorder do not have alarm signal cells in their

epidermis. In addition, these fishes have acellular bone and lack the Weberian apparatus. Most have a single-chambered gas bladder and are physoclistous, which means the gas bladder does not have a connection to the esophagus except at hatching.

Many popular aquarium fishes belong to families in Neoteleostei, such as Cichlidae, Poeciliidae, and Osphronemidae.

Cichlidae: This large family contains many popular aquarium fishes, including the freshwater angelfish, discus, oscar, and many more. Most cichlid species originate from Central or South America or Africa. These fish are often very colorful, particularly those originating from the African Rift Lakes. Many cichlid species are aggressive and territorial, requiring substantial cover to minimize injury caused by interspecific aggression. Wild-caught Amazonian cichlids (eg, freshwater angelfish and discus) generally prefer soft water and slightly acidic environments, whereas most African Rift Lake species thrive under hard water and slightly basic conditions.

Cichlids have a single-chambered gas bladder, which often is severely reduced in riverine species from Africa.

Cichlids are usually hardy and well adapted to aquariums. Many species are prone to intestinal parasitism from the flagellate *Spiroplasma*. African cichlids may be infected with *Cryptobia tubilans*, which causes a granulomatous gastritis, and some affected fish become extremely emaciated. Monogeneans are common findings on the gills of tank-raised discus.

Poeciliidae: This is another popular family of aquarium fishes, which includes guppies, swordtails, platies, and mollies. Some are euryhaline, such as the guppy and the molly, whereas the swordtail and platy are stenohaline to freshwater. These fishes are adapted to feed primarily at the water surface.

Poeciliids are susceptible to the bacterial diseases *F. columnare* and epitheliocystis.

Osphronemidae: This family, which includes gourami, paradise fish, and bettas, is well-adapted to life in shallow, slow-moving to stagnant water. This group of fishes has a unique air-breathing apparatus often called a labyrinth organ that consists of plates covered in respiratory epithelium. It is located above the gills in the branchial cavity and is deliberately filled with air when these fishes rise to the air-water interface. The bulk of the oxygen required is obtained via the labyrinth organ, and if these fishes are held so they cannot reach the air-water interface, they will drown.

The endocommensal *Protoopalina* is often seen in the intestine.

These fishes are susceptible to

F. columnare.

For an overview of common parasitic and viral diseases of aquarium fish, see TABLES 4 and 5. Susceptibility of specific families of fish to specific pathogens is implied; however, the absence of mention of a specific pathogen does not mean that the other families of fish are refractory.

MANAGEMENT

Many management principles applied to other species are equally relevant for fish, including taking a good history, considering appropriate diagnostic techniques, and being cognizant of therapeutic options, water quality issues, and quarantine and biosecurity procedures.

Physiology

Fish are poikilothermic, and all physiologic processes are greatly influenced by water temperature. In freshwater, the internal tissues of fish are hyperosmotic to the environment, whereas in saltwater they are hypoosmotic. Surface injuries to the skin make osmoregulation more difficult and may be of serious consequence because of the loss of fluid balance and circulatory collapse.

The structure of the fish kidney varies with the species; generally it is divided into an anterior "head" kidney, which is usually located anterior to the gas bladder, and a

posterior "caudal" kidney, which is retroperitoneal and ventral to the vertebral column. Hematopoietic, renal, and endocrine tissues are found in the kidney, with hematopoietic tissue located cranially and excretory tissue located caudally. Divalent ions are excreted principally via the kidney, and monovalent ions and nitrogenous excretions via the gills. Accordingly, lesions of the kidney and gills may seriously interfere with respiration, excretion, and fluid balance.

The gas bladder (also known as the swim or air bladder) in bony fish, which originates as an appendage of the foregut, regulates body buoyancy and may also be used for sound production. Physostomous fish have an open connection between the swim bladder and the GI tract, whereas physoclistous fish do not. Although a single chamber in most fish, the gas bladder consists of dual chambers in cyprinids and three chambers in cod and suckers belonging to the genus *Moxostoma*.

A sensory lateral line system along the sides of the body and head receives stimuli from the aquatic environment and mediates adaptive responses through the CNS.

Fish depend on increases in environmental temperature for efficient antibody production during infections (or after vaccinations), when most pathogens are replicating at a more rapid rate. The optimal temperature for antibody production varies with the species of fish (tropical, temperate, or coldwater). Extremes in environmental temperature (above or below that of the natural habitat) inhibit antibody production. Like T lymphocytes in other vertebrates, those in fish are responsible for cell-mediated immunity. Immunity is not as age dependent in fish as it is in other animals; young fish are usually immunocompetent and can be vaccinated successfully. Antibodies are found in the mucus of the fish skin and GI tract.

Although vaccination of fish against specific diseases has been economically important in preventing losses, there is a need for improved methodology. Advances include increased use of autogenous vaccines; several companies will work with veterinarians and their clients to develop custom vaccines for specific situations. A few vaccines (eg, for *Aeromonas salmonicida*) are available or in development for pet fish, particularly koi.

History

As with all species, a good history is critical to establish a diagnosis. Questions of

particular interest for fish cases include the number of animals affected, whether one species or multiple, the chronicity of the problem, and a thorough description of animal housing and care, including the volume and design of the system (*see* AQUATIC SYSTEMS, p 1766), number and size of animals stocked, species, new additions, use of quarantine, and previous medications. Owners can be asked to bring fish and water samples into the clinic, or the practitioner may wish to visit the site. Site visits allow the system to be more accurately evaluated and the behavior of fish readily observed. If fish are brought to the clinic, the owner should provide an animal showing the signs of concern. A live animal can be transported in a cooler with a battery-powered aerator. A separate water sample should be provided in a plastic bag and transported on ice. A minimum of 1 quart of tank water should be requested for analysis. If desired for recovery after anesthetizing the animal, a larger volume of tank water may be requested. Recently deceased specimens have diagnostic value and may be submitted to the veterinary clinic, or the owner may be directed to submit these to a laboratory experienced in fish necropsy and diagnostic testing (*see* below). Water samples should be submitted with necropsy specimens.

Necropsy and Diagnostic Techniques

Although the same principles are used in necropsy of fish as in other animals, great emphasis is placed on an accurate and thorough history, premortem signs, fresh necropsy material, and direct microscopic examination of fresh tissue smears and squash preparations. Fish decompose quickly, and many saprophytic microorganisms reproduce rapidly in the decaying tissues, which complicates isolation of pathogens unless samples are collected immediately after death. A general fish necropsy may include blood collection (premortem); biopsy of gill, skin, and fin tissues; bacterial or viral culture of internal organs; and histology. A veterinary clinic or diagnostic facility familiar with fish necropsy protocols and aquatic microbiology should be used. Whenever possible, live fish should be submitted. If the fish has just died, the eyes should be clear and the gills normal in coloration and texture. There should be no "dead fish" smell; however, some moribund fishes may have a strong odor. Freshly dead fish should be placed in a sturdy plastic bag and submitted on ice. A water sample should always be submitted with the fish. An animal

that has died and been placed in a freezer has limited diagnostic value, but freshly dead frozen fish may be useful for bacteriology, virology, or toxicology testing.

Fresh tissue samples of gill filaments, skin mucus, and fins should be collected, prepared as a wet mount, and examined under a light microscope at 40 $\times$, 100 $\times$, and 400 $\times$. Fresh water should be used to prepare wet mounts of external tissues from freshwater fish, and saltwater should be used to prepare wet mounts from marine fish. If uncertain, water from the tank or from the submitted water sample should be used. Ensuring that the salinity used to prepare mounts is similar to the salinity present in the environment should allow organisms to remain viable long enough for identification. Distilled water should not be used for tissue samples. Tissue should be examined for morphology and for the presence of parasites, bacteria, or fungal elements. Microscopic examination of internal organs is also recommended if the fish has been euthanized. Unstained sections of stomach and intestine should be examined for presence of parasites, and the lower intestine should be examined for flagellates. Unstained sections of spleen, anterior and posterior kidneys, and liver should be examined for presence of parasites, granulomas, or other anomalies. Wet-mount examination of fish tissues is crucial for diagnosis of most parasites.

Blood can be collected from a number of sites, and hematologic parameters measured. In fish >25–100 g, depending on species, the caudal vessels of the caudal peduncle, the duct of Cuvier (common cardinal vein), and the dorsal and ventral aortas are easily accessible. For smaller specimens that are to be euthanized, blood can be collected in a hematocrit tube immediately after euthanasia by severing the caudal peduncle and exposing the caudal vessels. Use of hematology and serum chemistry is limited, because normal values for many fish species are not readily available; however, the information may still be clinically useful. Lithium heparin is the anticoagulant of choice for most fish species, although EDTA is preferred for ictalurid catfishes, and plasma may be used for biochemistry tests. Serology may be diagnostic in certain cases (eg, heavy metal toxicity). Whole blood (1–2 drops) can be incubated in brain heart infusion broth at room temperature on an electric rotator. If cloudiness indicative of bacterial growth develops, a loop of the blood-broth mix can be used to attempt primary isolation of a systemic bacterial pathogen.

Fish should be euthanized and opened under sterile conditions. A sterile swab of posterior kidney, or other organ of interest, may be shipped to a laboratory in transport media, but primary isolation directly onto an enriched media (eg, tryptic soya agar enriched with 5% sheep blood) is preferable. Although blood agar supplemented with salt is helpful for marine fish, it is not necessary if an enriched blood agar is used. • Ordal's or similar cytophaga media should be available

for isolation of myxobacteria (slime bacteria, including *Flavobacterium columnare*). Sabouraud agar is an excellent all-purpose media for isolation of fungal agents. Lowenstein-Jensen or Middlebrook media is recommended for isolation of *Mycobacterium* spp. Mueller-Hinton is the media of choice for susceptibility testing of most common bacteria isolated from fish. If abscesses or other obvious anomalies are visible, those sites should also be cultured.

TABLE 6 FISH DISEASES OF REGULATORY CONCERN IN THE USA

Disease	Causative Agent	Susceptible Species
Viral hemorrhagic septicemia (Egtved disease)	<i>Novirhabdovirus</i> Family: Rhabdoviridae	Primary: salmonids (<i>Oncorhynchus</i> spp), turbo, herring and spat (<i>Clupea</i> spp), Japanese flounder Secondary: grayling, whitefish, pike, Atlantic and Pacific cod, haddock, many freshwater, marine, and estuarine species
Infectious hematopoietic necrosis	<i>Novirhabdovirus</i> Family: Rhabdoviridae	Primary: cultured salmonids (<i>Oncorhynchus</i> spp); lake trout and char (<i>Salvelinus</i> spp) are resistant
Spring viremia of carp	<i>Vesiculovirus</i> Family: Rhabdoviridae	Primary: carp (including koi, goldfish), sheatfish (European catfish), orfe, tench
Epizootic hematopoietic necrosis	<i>Ranavirus</i> Family: Iridoviridae	Primary: redfin perch Secondary: rainbow trout (wild and farmed fish)
Red sea bream iridoviral disease	<i>Megalocytivirus</i> Iridoviridae	Red sea bream, many other estuarine species, other marine species

In general, bacterial or fungal cultures taken from fish tissue should be incubated at room temperature (25°C). Some agents of concern will not grow at all at 37°C, the standard temperature for incubation of cultures taken from mammals. Agents of zoonotic concern, such as *Mycobacterium*, can be dual incubated at both 25°C and 37°C. An acid-fast stain should be available for bench-top staining of granulomatous material which, when positive, is strongly

suggestive of *Mycobacterium*. If fish are seen spinning or showing other behavioral indications of neurologic disease before death, brain cultures are indicated.

If viral disease is suspected, appropriate tissues may be collected. Specimens should include both fresh tissues placed in reagent ethanol and frozen tissues. Several viral diseases are of regulatory concern to veterinarians practicing fish medicine in the USA (see TABLE 6).

TABLE 6 FISH DISEASES OF REGULATORY CONCERN IN THE USA (continued)

Clinical Signs and Pathology	Temperature Range	Status in USA
Acute form: nonspecific hemorrhaging (eyes, fins, skin), darkening, exophthalmia, ascites Chronic form: few signs Neurologic form: spinning/flashing Gross: enlarged spleen, ascites, necrotic kidney Histologic: focal necrosis of kidney liver, spleen; hemorrhage in muscle	9°–12°C (48°–54°F) optimal	Present in wild populations, sporadic, limited distribution; endemic in Pacific Northwest and Alaska (wild salmonids, haddock, and cod); emerging disease in Great Lakes region
Rapidly increasing mortality (fish <1 yr), lethargic but sporadic bursts of rapid swimming occur, protruding vent, fecal casts, exophthalmic, pale gills, darkening, abdominal distention/ascitic fluid (possibly bloody)	10°–12°C (50°–54°F) optimal; rare >15°C (59°F)	Present in western USA, sporadic, limited distribution; endemic in Pacific Northwest and Alaska (wild salmonids); also present in parts of Europe and Asia
Nonspecific: darkening, exophthalmic, pale gills, distended abdomen, ascites, hemorrhage (gills, skin, eye), petechiae in organs (including swim bladder), protruding vent with thick mucoid fecal cast Coinfection with <i>Aeromonas</i> or other bacteria common	12°–22°C (54°–72°F)	USA is free (last occurred in captive fish in 2004, wild fish in 2007); occurs in eastern Europe, Russia, China, and Middle East
Acute and high mortality of redfin perch; darkening, ataxia, lethargy, hemorrhage around nares; morbidity and mortality of rainbow trout less severe Histologic: necrosis, renal hematopoietic tissues	Redfin perch: >12°C (54°F) Rainbow trout: 11°–17°C (52°–63°F) Experimental: 8°–21°C (46°–70°F)	Has never occurred in USA; endemic in Australia
Severe anemia, lethargic, pale gills, enlarged spleen		Has never occurred in USA; occurs in Japan and Taiwan

TABLE 6 FISH DISEASES OF REGULATORY CONCERN IN THE USA (continued)

Disease	Causative Agent	Susceptible Species
Infection with HPR-deleted or HPR0 Infectious salmon anemia	<i>Isavirus</i> Family: Orthomyxoviridae	Atlantic salmon Brown trout, sea trout, rainbow trout
Infection with salmonid alphavirus (pancreas disease or sleeping disease)	<i>Alphavirus</i> Family: Togaviridae	Atlantic salmon, rainbow trout, brown trout
Koi herpesvirus	Herpesviridae Cyprinid herpesvirus-3	Common carp and hybrids, including koi and ghost carp
Epizootic ulcerative syndrome (mycotic granulomatosis)	<i>Aphanomyces invadans</i>	Atlantic menhaden, striped mullet, many other freshwater and estuarine species; snakeheads, barbs (<i>Puntias</i> spp) sensitive; gouramis, goldfish and other ornamentals susceptible; tilapia resistant
<i>Gyrodactylus</i> (<i>Gyrodactylus salaris</i> only)	Monogenea <i>Gyrodactylus salaris</i> only	Atlantic salmon, rainbow trout, brook trout, North American lake trout, brown trout, grayling arctic char

Tissue sections no larger than 1 cm³ should be placed in 10% neutral buffered formalin for histopathology. After 24 hr of fixation, they should be removed and placed in reagent alcohol in case molecular diagnostic techniques will be required.

Therapeutic Considerations

Therapy for pet and ornamental fish is often based on environmental management followed by the use of targeted therapy to control specific pathogens. Use of prophylactic medication in the absence of diagnostic testing is strongly discouraged and may contribute to resistant bacterial infection and other complications.

Drug therapy can be provided via several routes of administration, including exposure by bath (adding medication to water), medicated feed, injection, or topical administration. Generally speaking, bath and topical treatments are most useful for external infections, whereas medicated food and injection are most appropriate for internal infections.

Using a bath treatment requires accurate measurement of the volume of water to be treated. Volume of a rectangular tank is

calculated by multiplying measurements of the length, width, and depth. Volume of a circular tank is calculated by multiplying 3.14 by the radius squared by the depth. To calculate directly into liters, measurements should be in cm and multiplied by 0.001. If the measurements are made in feet, the result will be in cubic feet; cubic feet can be converted to gallons by multiplying by 7.481. If the container is oddly shaped, volume may be calculated mathematically, but it may be easier to purchase a flow meter to measure the volume required to fill the tank. Alternatively, the volume of inflowing water per minute can be measured by determining how long it takes to fill a 1-L graduated cylinder (or 5-gal. bucket). Using that information, determining how long it takes to fill a tank or ornamental pond can provide a fairly accurate assessment of volume.

Some medicated feeds can be purchased commercially for aquaculture or pet fish. Custom-made medicated feeds can be prepared for use in ornamental fish. Flake, pellet, or gel diets can be used as a base for medicated food for pet fish. Cooking oil spray is an effective binder for use with

TABLE 6 FISH DISEASES OF REGULATORY CONCERN IN THE USA (*continued*)

Clinical Signs and Pathology	Temperature Range	Status in USA
Pale gills, severe anemia (PCV <10%), swollen liver (black/brown color), ascites, petechiae of viscera, mesenteric fat, swim bladder	In vitro: Maximum replication 15°C (59°F) No replication 25°C (77°F)	Present in northeast USA, sporadic, limited distribution; endemic in Maine, New Brunswick, Scotland, and Norway
Necrosis of exocrine pancreas, heart and skeletal muscle changes	12°–15°C (54°–59°F)	Has not occurred in USA; detected in Ireland, UK, France, Germany, Italy, Spain, Switzerland, Poland, and Norway
Severe necrosis gill tissue	22°–25.5°C (72°–78°F) optimal ^a	Present in USA, sporadic, widely distributed
Necrotizing deep ulcers (penetrate body wall), granulomatous tissue response; deep ulcers with red centers, white rims; invasive nonseptate hyphae (culture possible but difficult)	<25°C (77°F) (reduced salinity also contributes in brackish systems)	Present in USA, sporadic, limited distribution
		Has never occurred in USA

^a Mortalities stop at >30°C (86°F), but survivors remain carriers.

pelleted or flake foods for ornamental fish. The addition of medication to commercially available gel diets is easily done as the gel cools. In general, medication should not be added when the gelatin is hot, because some medications, particularly oxytetracycline, are heat labile.

Injections can be given either IM or intracoelomic (IC). IM injections are given in the epaxial muscles, lateral to the dorsal fin. Injection of some drugs can cause muscle necrosis, so it is important to alternate injection sites and to limit injections to every 3 days unless required more often. To administer IC injections, fish should be placed head downward in dorsal recumbency to move internal organs away from the injection site, which should be anterior to the anus, just off the ventral midline. Topical treatments, usually in ointment form, should be applied directly to the external lesion(s). The fish can be manually restrained, usually without removing the entire animal from the water. The area to which the treatment is applied should be held out of the water for several seconds (<1 min) to allow some absorption

before returning the fish to the water.

Repeated applications may be necessary.

Sunburn can occur in surface-swimming fish or can be induced (even in bottom-dwelling species) by feeding photodynamic drugs such as phenothiazine, although ultraviolet light penetrates water poorly. Affected fish will have visible lesions along the dorsal surface. Providing shade solves the problem.

FDA-approved Drugs and Regulatory Concerns: FDA-approved therapeutic options in fish are limited; however, there has been significant progress in approvals in the past few years, and this trend is expected to continue. The FDA Web site (www.fda.gov/cvm/aqualibtoc.htm) is the best resource for current information on the status of drugs and chemicals. In many cases, therapeutic management of fish other than catfish or salmonids requires extra-label use of drugs. A new mechanism called indexing is being developed by the FDA to allow for legal use of nonapproved drugs in ornamental fish. The following information is intended for use in pet fish medicine.

TABLE 7 FDA-APPROVED DRUGS FOR AQUACULTURE USE IN THE USA (2014)

Drug	Species	Indications
IMMERSION		
Formalin (Parasite-S®, Formalin-F™, Formacide-B)	All finfish	Control external protozoa (<i>Chilodonella</i> , <i>Ichthyobodo</i> , <i>Epistylis</i> , <i>Ichthyophthirius</i> , <i>Ambiphyra</i> , <i>Trichodina</i> spp), <i>Tetrahymena</i> spp and monogeneans (<i>Cleidodiscus</i> , <i>Dactylogyrus</i> , <i>Gyrodactylus</i> spp)
	All finfish eggs	Control fungi of the family Saprolegniaceae
	Penaeid shrimp	Control protozoan parasites (<i>Bodo</i> , <i>Epistylis</i> , and <i>Zoothamnium</i> spp)
